Motivated by the Coxeter complex associated to a Coxeter system (W, S), we introduce a simplicial regular cell complex $\Delta(G, S)$ with a G-action associated to any pair (G, S) where G is a group and S is a finite set of generators for G which is minimal with respect to inclusion.

We examine the topology of $\Delta(G, S)$, and in particular the representations of G on its homology groups. We look closely at the case of the symmetric group $\mathfrak{S}_n$ minimally generated by (not necessarily adjacent) transpositions, and their type-selected subcomplexes. These include not only the Coxeter complexes of type A, but also the well-studied chessboard complexes.

Keywords: Coxeter complex, simplicial poset, Boolean complex, chessboard complex, Shephard group, unitary reflection group, simplex of groups, homology representation

1 Introduction.

The Coxeter complex $\Delta(W, S)$ associated to a Coxeter system (W, S) is a beautiful simplicial complex which encodes the structure of the Weyl chambers for W. Its poset of faces has a very simple description as the poset of cosets of parabolic subgroups ordered by reverse inclusion [20, §1.15]. This description has many consequences for its topology and homology representations.

In this paper, we propose a more general construction of a simplicial cell complex for a pair (G, S) where G is a group and S is any finite generating set which is minimal with respect to inclusion. We observe a number of easy general facts about these complexes in Section 2, and give many examples in Section 3.

In Section 4, we focus on the case where $G = \mathfrak{S}_n$, the symmetric group, and S is a set of transpositions. Here S corresponds to a choice of spanning tree on n vertices, and (G, S) forms a Coxeter system exactly when this tree is a path. There turn out to be many constraints on the homology representations of $\Delta(G, S)$ in this case, some related to the properties of the spanning tree. In particular, we are led naturally to consider type-selected subcomplexes of $\Delta(G, S)$, which turn out to include the much-studied chessboard complexes as a special case.

In Section 5, we look even more closely at the special case where the spanning tree has only one branched vertex (i.e. vertex of degree at least three). Here one can prove further constraints on the homology, and our results are most complete when the unique branched vertex has degree exactly three.

2 Generalities.

2.1 The cell complex and its face poset.

This section gives the basic construction, and explores some of its general properties. Good references for some of the terminology and facts regarding posets, simplicial complexes and cell complexes are [3] and [4].

Let G be a (finitely generated) group, and S a finite generating set for G which is minimal with respect to inclusion. Given any subset $J \subseteq S$, let G_J denote the subgroup $\langle J \rangle$ generated by J in G (by analogy with Coxeter groups, call G_J a *parabolic subgroup*). Form the poset $P(G, S)$ whose elements are the cosets $\{gG_J : g \in G, J \subseteq S\}$ with ordering by *reverse inclusion*, i.e. $gG_J < g'G_{J'}$ if $gG_J \supset g'G_{J'}$.

Proposition 2.1. *$P(G, S)$ is a simplicial poset in the sense of Stanley [31], that is, every lower interval in $P(G, S)$ is isomorphic to a Boolean algebra.*

Proof. It suffices to show that if $gG_K \subseteq g'G_{K'}$ then $g'G_{K'} = gG_{K'}$ and $K \subseteq K'$, since then the interval below gG_K in $P(G, S)$ would consist of $\{gG_J | J \supseteq K\}$, and hence be isomorphic to the Boolean algebra 2^{S-K} via the map $gG_J \mapsto S - J$. To show this, we have these implications:

$$gG_K \subseteq g'G_{K'} \Rightarrow 1 \in G_K \subseteq g^{-1}g'G_{K'}$$
$$\Rightarrow g^{-1}g'G_{K'} = G_{K'}$$
$$\Rightarrow g'G_{K'} = gG_{K'}$$
$$\Rightarrow gG_K \subseteq gG_{K'}$$
$$\Rightarrow G_K \subseteq G_{K'}$$
$$\Rightarrow K \subseteq K'$$

where the last implication uses the minimality of the generating set S. $\square$

A simplicial poset P is *balanced* if there is a coloring of the atoms of P so that every maximal element of P lies above exactly one atom of each color. Clearly $P(G, S)$ is balanced with color set S by assigning the atom $gG_{S-\{s\}}$ the color s.

We have the following immediate consequence.

Corollary 2.2. *There is a unique (up to isomorphism) balanced regular cell complex of Boolean type [4] or Boolean complex [16] having $P(G, S)$ as its poset of faces.* $\square$

We denote this regular cell complex having face poset $P(G, S)$ by $\Delta(G, S)$; it will be our main object of study.

The regular nature of the face poset $P(G, S)$ implies that the Boolean complex $\Delta(G, S)$ enjoys many of the pleasant properties of Coxeter complexes, which we review here.

Recall that a pure d-dimensional cell complex is *gallery-connected* if any pair F, F' of d-faces are connected by a path

$$F = F_0, F_1, \ldots, F_{r-1}, F_r = F'$$

of d-faces in which F_i and F_{i+1} share a $(d-1)$-face for each i.

The next proposition is immediate from the definition of $P(G, S)$.

Proposition 2.3.   *(i) $\Delta(G,S)$ is a pure Boolean complex of dimension $|S|-1$, which is gallery-connected and balanced with color set S.*

 (ii) The group G acts transitively on its maximal faces.

(iii) Stabilizers of codimension 1 faces are non-trivial cyclic groups, and the stabilizer of an arbitrary face is the subgroup generated by the stabilizers of the codimension 1 faces containing it. In particular, the transitive G-action on maximal faces is simply transitive.

Remark 2.4. It is not hard to check that the properties listed in the preceding proposition completely characterize the Boolean complexes $\Delta(G,S)$. To be precise, if one assumes that Δ is a balanced Boolean complex carrying a G-action satisfying properties (i), (ii) listed above, then G has a minimal generating set S consisting of a set of generators for the cyclic groups that stabilize the codimension 1 faces of some fixed maximal face of Δ, and $\Delta \cong \Delta(G,S)$.

We also note[‡] that $\Delta(G,S)$ is a very special case of what has been called a *(developable) simplex of groups* (see [18, §2.4] and [30]).

Although $\Delta(G,S)$ has simplicial cells, it need not be a simplicial complex; see Example 3.4 below. However, there is a simple criterion for this to occur. Given any Boolean complex Δ with vertex set (0-cells) V, define an abstract simplicial complex $\overline{\Delta}$ on the same vertex set V as follows: $F \subset V$ spans a face of $\overline{\Delta}$ if and only if there exists at least one cell of Δ containing all the vertices in F. Given any cell σ of Δ, let $\mathrm{vertices}(\sigma)$ denote its set of vertices. The following fact about Boolean complexes is then straightforward.

Proposition 2.5. *For any Boolean complex, the map*

$$f: \begin{array}{ccc} \Delta & \to & \overline{\Delta} \\ \sigma & \mapsto & \mathrm{vertices}(\sigma) \end{array}$$

induces a dimension-preserving simplicial surjection.

It is an isomorphism if and only if every cell σ of Δ is uniquely determined by its set of vertices, or equivalently, if and only if Δ is a simplicial complex. $\qquad\square$

In the case of $\Delta = \Delta(G,S)$, there is a natural alternative description of $\overline{\Delta}$ which ties it in with *Tits coset complexes*, as studied in [5] and [17]. Let

$$\mathcal{C}(G,S) = \{gG_{S-s} : g \in G, s \in S\}.$$

denote the covering of the set G by the cosets of maximal (proper) parabolic subgroups. Let $\mathcal{N}(C(G,S))$ be the *nerve* of this covering, that is, the abstract simplicial complex with typical vertex labeled gG_{S-s} and a face $\{g_iG_{S-s_i}\}_{i=1}^r$ whenever $\bigcap_{i=1}^r g_iG_{S-s_i} \neq \varnothing$.

[‡] Thanks to Mike Davis for pointing this out.

Corollary 2.6. *The simplicial complex* $\overline{\Delta(G,S)}$ *which is associated to the Boolean complex* $\Delta(G,S)$ *is* $\mathcal{N}(C(G,S))$. *Hence the map*

$$
\begin{array}{rcl}
f: & \Delta(G,S) & \to & \mathcal{N}(C(G,S)) \\
& gG_J & \mapsto & \{gG_{S-s} : s \in S - J\}
\end{array}
$$

induces a dimension-preserving G-equivariant cellular surjection.
  It is an isomorphism if and only if (G,S) satisfies the intersection condition

$$
\bigcap_{s\in S-J} G_{S-s} = G_J \qquad \text{for every } J \subset S, \tag{2.1}
$$

or equivalently, if and only if $\Delta(G,S)$ is a simplicial complex.

Proof. The first assertion is a restatement of the definitions. The rest is then a straightforward application of Proposition 2.5. The condition that every cell is uniquely determined by its vertices translates into the intersection condition: we always have an inclusion

$$
G_J \subseteq \bigcap_{s\in S-J} G_{S-s},
$$

but whenever there exists $g \in \left(\bigcap_{s\in S-J} G_{S-s}\right) - G_J$ then $gG_J \neq G_J$ give two different faces of $\Delta(G,S)$ with the same vertex set. $\square$

Remark 2.7.
All of the previous results easily generalize to a relative framework that includes *Tits buildings* associated to groups with a BN-pair. Let G be a group, and B any subgroup. Given a finite subset $S \subset G$ which is minimal with respect to inclusion having the property that $G = \langle B, S \rangle$, define subgroups $P_J := \langle B, J \rangle$ for $J \subseteq S$. Then the poset $P(G,B,S)$ whose elements are the cosets $\{gP_J : g \in G, J \subseteq S\}$ with ordering by reverse inclusion is again a simplicial poset, so it is the face poset of a unique regular cell complex $\Delta(G,B,S)$. This $\Delta(G,B,S)$ shares many of the properties of $\Delta(G,S)$ proven above. In the case where G is a group with BN-pair having associated Coxeter system (W,S), this $\Delta(G,B,S)$ is the usual Tits building.

Remark 2.8. We should mention that Brown [7] recently studied a (different) topological space built from proper cosets of a group ordered by inclusion. We are not aware of a direct link with his work.

2.2 Pseudomanifolds, links, and singularities.

Note that maximal faces of $\Delta(G,S)$ are indexed by cosets $gG_\varnothing = \{g\}$ and hence correspond to the elements of G. Codimension one faces are indexed by cosets $gG_{\{s\}}$, and such a face will lie in as many facets as the order of s in G. Since $\Delta(G,S)$ is gallery-connected, this implies the following.

Proposition 2.9. $\Delta(W,S)$ *is a pseudomanifold if and only if S contains only involutions. When this is the case,* $\Delta(W,S)$ *is orientable as a pseudomanifold if and only if the set map*

$$
\begin{array}{rcl}
\epsilon: & S & \to & \mathbb{Z}^\times = \{\pm 1\} \\
& s & \mapsto & -1
\end{array}
$$

extends to a group homomorphism $G \xrightarrow{\epsilon} \mathbb{Z}^{\times}$. In this situation,

$$H_{|S|-1}(\Delta(G, S), \mathbb{Z}) \cong \mathbb{Z}$$

and the homomorphism ϵ coincides with the action of G on this top homology.

In the cases where $\Delta(G, S)$ is a pseudomanifold, it is often singular. The following trivial proposition about the links of its faces is helpful in understanding its singularities (see [13, §3.3] for a careful discussion of links in simplicial posets).

Proposition 2.10. *The link of the face indexed by gG_J in $\Delta(G, S)$ is isomorphic to $\Delta(G_J, J)$.* □

Note that this implies that the singularities of $\Delta(G, S)$ are fairly easy to understand by induction on $|S|$. In particular, we have the following.

Corollary 2.11. *When S contains only involutions, the singularities of the pseudomanifold $\Delta(G, S)$ have codimension at least 3. In particular, when S consists of involutions and $|S| \le 3$, then $\Delta(G, S)$ is smooth.*

Proof. Use the previous proposition and Proposition 2.3. The link of every codimension 2 face is a gallery-connected pseudomanifold of dimension 1 and hence a sphere. □

2.3 Morphisms and quotients.

Given pairs (G, S) and $(\hat{G}, \hat{S})$ as above, say that a group homomorphism $\phi : \hat{G} \to G$ is a *morphism of pairs* if $\phi(\hat{S}) \subseteq S$. The following proposition is straightforward.

Proposition 2.12. *The map on cosets*

$$\hat{g}\hat{G}_{\hat{J}} \mapsto \phi(\hat{g})G_{\phi(\hat{J})}$$

induces an order-preserving map of posets $P(\hat{G}, \hat{S}) \to P(G, S)$ and hence also a map of Boolean complexes $\Delta(\hat{G}, \hat{S}) \to \Delta(G, S)$.

Furthermore, surjectivity of the following maps are equivalent:

(i) $\Delta(\hat{G}, \hat{S}) \to \Delta(G, S)$,

(ii) $P(\hat{G}, \hat{S}) \to P(G, S)$,

(iii) $\hat{G} \to G$,

(iv) $\hat{S} \to S$.

Lastly, the map $\Delta(\hat{G}, \hat{S}) \to \Delta(G, S)$ is dimension-preserving if and only if the map $\hat{S} \to S$ is injective. □

Morphisms of pairs relate to a natural construction of a *quotient complex* $H \backslash \Delta(G, S)$ for a subgroup H of G (here H acts on cosets gG_J by left-translation). Because the left-translation action of H on $\Delta(G, S)$ is type-preserving (so in particular, a face is stabilized by a group element if and only if it is stabilized pointwise), this quotient is again a Boolean complex whose geometric realization as a topological space is homeomorphic to the quotient space of the geometric realization of $\Delta(G, S)$ by the action of H. Its face poset $H \backslash P(G, S)$ has the following description involving *double cosets HgG_J*: the elements of $H \backslash P(G, S)$ are pairs (J, HgG_J) where $J \subseteq S$ and $g \in G$, and we define

$$(J, HgG_J) \le (J', Hg'G_{J'}) \text{ if } J \supseteq J' \text{ and } HgG_J \supseteq Hg'G_{J'}.$$

Remark 2.13.
The previous definition of $H\backslash P(G, S)$ corrects [24, pp. 12-13], where it was incorrectly asserted that $H\backslash P(G, S)$ is the poset of all double cosets $\{HgG_J : g \in G, J \subseteq S\}$ ordered by reverse inclusion. Fortunately, this has no effect on the later results of [24], as they proceed from the (correct) assumption that the faces of $H\backslash\Delta(G, S)$ having color set $S - J$ are in bijection with double cosets of the form HgG_J inside G.

The slight subtlety here is that whenever there exist coincidences $HgG_J = HgG_{J'}$ for $J \neq J'$ (as happens in many interesting examples), there will exist different poset elements $(J, HgG_J) \neq (J', HgG_{J'})$ with the same double coset in the second coordinate (but different color sets: $S - J \neq S - J'$).

A good example of this occurs when $H = G$, so that $HgG_J = G$ for all $g \in G$ and all $J \subseteq S$. Then the quotient complex $G\backslash\Delta(G, S)$ is an $(|S| - 1)$-simplex whose face poset $G\backslash P(G, S)$ has elements (J, G) for $J \subseteq S$, ordered by reverse inclusion on the first coordinate.

Proposition 2.14. *Let $\phi : (\hat{G}, \hat{S}) \to (G, S)$ be a morphism of pairs which is bijective when restricted to a map $\hat{S} \to S$, and let*

$$K := \ker(\phi : \hat{G} \to G).$$

Then there is an isomorphism of Boolean complexes

$$K\backslash\Delta(\hat{G}, \hat{S}) \to \Delta(G, S)$$

induced by the isomorphism of face posets given by

$$(\hat{J}, K\hat{g}\hat{G}_{\hat{j}}) \mapsto \phi(\hat{g})G_{\phi(\hat{J})}.$$

Proof. Using the fact that K is a normal subgroup, so that

$$K\hat{g}\hat{G}_{\hat{j}} = \hat{g}K\hat{G}_{\hat{j}} = \hat{g}\hat{G}_{\hat{j}}K$$

and the fact that $G \cong \hat{G}/K$, it is easy to check that the above map of face posets is indeed an isomorphism.
$\square$

Corollary 2.15. *When (G, S) has S consisting of involutions, $\Delta(G, S)$ is a quotient of the Coxeter complex $\Delta(\hat{W}, \hat{S})$ for the Coxeter system $(\hat{W}, \hat{S})$ in which the order of $\hat{s}\hat{s}'$ in $\hat{W}$ is defined to be the same as the order of ss' in G.*
$\square$

As will been seen in the next section, this corollary can be useful for visualizing examples where $|S|$ is small. Here one can often identify the Coxeter complex $\Delta(\hat{W}, \hat{S})$ either as a sphere or affine space (when $(\hat{W}, \hat{S})$ is finite or affine), and visualize the action of K on this space giving rise to the quotient space $\Delta(G, S)$. P. Webb has also pointed out to us that many finite simple groups have involutive generating sets whose presentations (as listed in the Atlas [11]) exhibit them as quotients of Coxeter groups by easily described subgroups. See also [24] for some combinatorics related to quotients of Coxeter complexes.

2.4 Homology representations.

From the homological viewpoint, a pleasant feature of $\Delta(G, S)$ is the simple description of its cellular chain complex. Given a coefficient ring R, as $R[G]$-modules, the (augmented) cellular chain groups

$C_\bullet(\Delta(G,S), R)$ with coefficients in R can be described in terms of coset representations $R[G/H]$:

$$0 \to R[G] \to \bigoplus_{s \in S} R[G/G_{\{s\}}] \to$$

$$\cdots \to \bigoplus_{J \subseteq S:|J|=i} R[G/G_J] \to \cdots \tag{2.2}$$

$$\to \bigoplus_{s \in S} R[G/G_{S-s}] \to R \to 0.$$

Here the boundary maps can be defined componentwise, and up to sign, in each component are the natural maps $R[G/K] \to R[G/H]$ with $[gK] \mapsto [gH]$ whenever $K \subseteq H$. The homological indexing is given by

$$C_i(\Delta(G,S), R) := \bigoplus_{J \subseteq S:|J|=|S|-1-i} R[G/G_J].$$

One consequence of this is an expression for the *(reduced) Euler characteristic* when G is finite:

$$\chi(\Delta(G,S)) = \sum_{J \subset S} (-1)^{|S|-|J|-1} [G:G_J] = |G| \sum_{J \subset S} \frac{(-1)^{|S|-|J|-1}}{|G_J|}. \tag{2.3}$$

Another immediate consequence is the following description of the top homology as an intersection of kernels.

Corollary 2.16.

$$H_{|S|-1}(\Delta(G,S), R) = \bigcap_{s \in S} \ker(R[G] \to R[G/G_{\{s\}}]).$$

$\square$

The previous corollary already tells us something, when G is finite, about the occurrence of one-dimensional representations of G in the top homology considered as a $\mathbb{C}[G]$-module. We use the notation $\langle V, W \rangle$ to denote the inner product of the complex characters of two $\mathbb{C}[G]$-modules V and W. Recall that for any irreducible $\mathbb{C}[G]$-module W, the quantity $\langle V, W \rangle$ computes the multiplicity of W in V. Given a subgroup H of G, let $V \downarrow_H^G$ and $V \uparrow_H^G$ denote the restriction and induction of representations to and from H respectively.

Proposition 2.17. *Let $\chi : G \to \mathbb{C}^\times$ be a one-dimensional representation of G. Then*

$$\langle H_{|S|-1}(\Delta(G,S), \mathbb{C}), \ \chi \rangle = \begin{cases} 1 & \text{if for all } \ s \in S, \text{ one has } \chi \downarrow_{G_{\{s\}}}^G \neq 1 \\ 0 & \text{else.} \end{cases}$$

Proof. One knows that $\mathbb{C}[G] = C_{|S|-1}(\Delta(G,S), \mathbb{C})$ carries exactly one copy of each one-dimensional representation χ, namely as the $\mathbb{C}$-span of the element

$$\sum_{g \in G} \chi(g^{-1})g.$$

It is then easy to check that $\chi \subseteq \ker(\mathbb{C}[G] \to \mathbb{C}[G/G_{\{s\}}])$ if and only if $\chi \downarrow_{G_{\{s\}}}^G \neq 1$, from which the statement follows. $\square$

2.5 Type selection.

Whenever one has a balanced Boolean complex Δ with color set S, one can talk about its *type-selected* or *color-selected subcomplex* Δ_J for $J \subseteq S$, that is, Δ_J is the subcomplex induced on the set of vertices whose color lies in J. Since the face indexed by gG_J in $\Delta(G, S)$ has color set $S - J$, the type-selected subcomplex $\Delta(G, S)_J$ is the unique Boolean complex whose face poset is

$$P(G, S)_J := \{ \text{ cosets } gG_K : S - J \subseteq K, g \in G\}$$

ordered by reverse-inclusion.

The following proposition is the key to many deletion-contraction arguments in Section 4.

Proposition 2.18. *If G is a group, S is a finite minimal generating set and $s \in J \subseteq S$ then there is a short exact sequence of complexes of $\mathbb{C}[G]$-modules*

$$0 \to C_\bullet(\Delta(G, S)_{J-s}) \to C_\bullet(\Delta(G, S)_J)$$
$$\to (C_\bullet(\Delta(G_{S-s}, S - s)_{J-s}))[1] \uparrow_{G_{S-s}}^{G} \to 0.$$

Here $C_\bullet[1]$ denotes the chain complex $C_\bullet$ with degree shift by 1, i.e. $C_i[1] = C_{i-1}$, and $\uparrow_H^G$ denotes induction of a representation from a subgroup H to G.

Proof. The injective map is induced from the inclusion

$$\Delta(G, S)_{J-s} \hookrightarrow \Delta(G, S)_J.$$

The rest is straightforward. $\square$

Remark 2.19. The short exact sequence in Proposition 2.18 actually reflects the cofibration sequence

$$\Delta(G, S)_{J-s} \hookrightarrow \Delta(G, S)_J \twoheadrightarrow \bigvee_{[G:G_{S-s}]} \mathrm{Susp}\,(\Delta(G_{S-s}, S - s)_{J-s})$$

or in other words, the quotient space $\Delta(G, S)_J/\Delta(G, S)_{J-s}$ is homotopy equivalent to the one-point wedge of $[G : G_{S-\{s\}}]$ copies of the suspension of $\Delta(G_{S-\{s\}}, S - \{s\})_{J-\{s\}}$. This generalizes [8, Proposition 2.1].
3   Examples.

3.1 Euclidean reflection groups.

A Euclidean reflection group W is a finite group acting faithfully on a Euclidean space V and generated by linear reflections[§]. Such groups are known to have a minimal generating set of reflections S which endows (W, S) with the structure of a *Coxeter system* (see [20, Chapter 1]). In this case, $\Delta(W, S)$ is called the *Coxeter complex*, and the description of its poset of faces $P(W, S)$ was our motivating example. Here $\Delta(W, S)$ triangulates the sphere $\mathbb{S}^{\dim V - 1}$, and may be identified with the simplicial decomposition of the unit sphere in V by the reflecting hyperplanes for the reflections in W. There is an extensive literature on Coxeter complexes; see [6] for some references.

[§] Some authors might apply the term "Euclidean reflection group" to the case where W is possibly infinite but generated by affine reflections. For this reason, one should perhaps call the finite reflection groups that we consider above *spherical reflection groups*.

Fig. 1: Examples of $\Delta(G,S)$ which are 2-tori. In (a), $G = \mathfrak{S}_4$ and $S = (12), (13), (14)$ (cf. [8, Figure 2]). In (b), G is group of 4×4 unitriangular matrices over $\mathbb{F}_2$ and S is the subset of unitriangular matrices having one non-zero superdiagonal entry and all other entries above the diagonal zero.

On the other hand, if we choose *any* minimal generating set S of reflections for W, one can still form $\Delta(W,S)$, and the fact that the determinant or sign representation $\epsilon : W \to \mathbb{Z}^\times$ is well-defined implies that it will be an orientable pseudomanifold by Proposition 2.9.

Example 3.1. The first non-trivial example of the previous discussion occurs when $W = \mathfrak{S}_4$ the symmetric group on 4 letters, and

$$S = \{s_1 = (12), s_2 = (13), s_3 = (14)\},$$

where (ij) denotes the transposition which swaps i and j. Since $|S| = 3$, we know that $\Delta(W,S)$ is an orientable surface by Proposition 2.11. Its Euler characteristic is easily calculated as in (2.3) to be 0, so it must be a 2-torus.

One can apply Corollary 2.15 to visualize this torus. Consider the affine Coxeter system $\tilde{A}_2 = (\hat{W}, \hat{S})$ where $\hat{S} = \{\hat{s}_1, \hat{s}_2, \hat{s}_3\}$ satisfy the following relations: $(\hat{s}_i)^2 = (\hat{s}_i \hat{s}_j)^3 = 1$ for all $i \neq j$. One can check directly that the s_i's satisfy all of these same relations, along with further relations of the form $(s_i s_j s_i s_k)^2 = 1$ with $\{i,j,k\} = \{1,2,3\}$. Thus if K is the subgroup of $\hat{W}$ generated by all words of the form $(\hat{s}_i \hat{s}_j \hat{s}_i \hat{s}_k)^2$ as above, then $\Delta(W,S)$ is isomorphic to the quotient of the affine Coxeter complex $\Delta(\hat{W}, \hat{S})$ by the action of K. This affine Coxeter complex is a tessellation of the 2-plane by equilateral triangles, and K acts as a lattice of translations on this 2-plane, leaving a quotient homeomorphic to the 2-torus, which is $\Delta(W,S)$, as in Figure 3.1 (a).

It turns out that in this example $\Delta(W,S)$ is a simplicial complex (see Proposition 4.2 below), and that it is isomorphic to the 3×4 *chessboard complex*, first considered by Garst [17] in the context of coset complexes of groups, and later by Björner, Lovasz, Vrecica and Zivaljevic [8] and many other authors (see Example 4.5 below). In [8, p. 30] it was also pointed out that it is a 2-torus.

In Section 4, we discuss the case where $W = \mathfrak{S}_n$ in more detail.

Example 3.2. The previous example raises the question of which manifolds can be achieved as $\Delta(G, S)$. The authors thank M. Özaydin for pointing out the following simple construction which achieves all orientable surfaces (orientable 2-manifolds) in this way. Let

$$
\begin{aligned}
G &:= D_{4n} \times \mathbb{Z}/2\mathbb{Z} \\
&= \langle r, s, t : 1 = r^2 = s^2 = t^2 = (rs)^{2n} = (rt)^2 = (st)^2 \rangle
\end{aligned}
$$

where D_m denotes the dihedral group of order m. We choose $S := \{r, s, rt\}$. Since the elements of S are involutions, and the map sending r, s to -1 and t to $+1$ extends to a homomorphism of G that sends all elements of S to -1, we must have that $\Delta(G, S)$ is an orientable surface, and then a quick Euler characteristic computation shows that it has genus $n - 1$.

3.2   Unitary reflection groups.

A unitary reflection group is a finite group acting faithfully on a unitary space (a finite dimensional complex vector space with positive definite Hermitian bilinear form) and generated by unitary reflections, that is, elements of finite order which fix some hyperplane. Such groups were classified by Shephard and Todd [28], and contain many interesting examples. There is one infinite family of such groups $G(de, e, r)$, consisting of the $r \times r$ matrices with one non-zero entry in each row and column for which all non-zero entries are $(de)^{th}$ roots of unity, and for which the product of the non-zero entries is a dth root of unity.

Unfortunately, unitary reflection groups seem to lack distinguished sets of generators in general. However, there are at least two well-behaved subclasses of unitary reflection groups which have them

- the *complexifications* of Euclidean reflection groups (i.e. extending the action of a Euclidean reflection group acting on $\mathbb{R}^n$ to $\mathbb{C}^n$), and

- the *Shephard groups* introduced by Shephard [27] and studied further by Coxeter [12], which are the automorphism groups of *regular complex polytopes*.

For Shephard groups and their distinguished generating sets S, the complex $\Delta(G, S)$ has many different descriptions, including some which make no reference to the choice of the generators S- see Orlik [21]. In this situation, $\Delta(G, S)$ turns out to be a simplicial complex which is homotopy equivalent to a wedge of spheres of dimension $|S| - 1$, and the homology representation $H_{|S|-1}(\Delta(G, S), \mathbb{Z})$ has many beautiful guises, which are studied in [22].

Remark 3.3. Motivated by the Coxeter and Shephard cases, along with Corollary 2.16 and Proposition 2.17, one might naively hope that $H_{|S|-1}(\Delta(G, S), \mathbb{Z})$ carries some *canonical* representation of G, independent of the choice of the minimal generators S, say for some "nice" groups G.

Unfortunately, even for some of the groups in the infinite family $G(de, e, r)$ this appears to fail, e.g. the rank of $H_{|S|-1}(\Delta(G, S), \mathbb{Z})$ can depend on the choice of minimal generators. For example, if $G = G(6, 2, 2)$, define unitary reflections

$$
s_0 = \begin{bmatrix} \omega^2 & 0 \\ 0 & 1 \end{bmatrix}, \quad s_1 = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}, \quad s_2 = \begin{bmatrix} 0 & \omega^{-1} \\ \omega & 0 \end{bmatrix}, \quad s_2' = \begin{bmatrix} 0 & -1 \\ -1 & 0 \end{bmatrix}
$$

where ω is any primitive sixth root of unity. Letting

$$S := \{s_0, s_1, s_2\}$$
$$S' := \{s_0, s_1, s_2'\},$$

one can easily check that both S and S' are minimal generating sets of unitary reflections for G. However a computer calculation shows that

$$H_2(\Delta(G, S), \mathbb{Z}) \cong \mathbb{Z}^2$$
$$H_2(\Delta(G, S'), \mathbb{Z}) \cong \mathbb{Z}^4.$$

Nevertheless, a happy situation occurs when the unitary reflection group G is generated by unitary reflections of order two (involutions). Perhaps surprisingly, there are many instances where this occurs, even when the group is *not* the complexification of some Euclidean reflection group (see e.g. the tables at the end of [9]). Any minimal choice of generating involutive reflections S for such a group G will give rise to an orientable pseudomanifold $\Delta(G, S)$ (via Proposition 2.9) since the determinant representation is a well-defined homomorphism $\epsilon : G \to \mathbb{Z}^\times$.

Example 3.4. Within the infinite family $G(de, e, r)$, the groups in the subfamily $G(2e, e, r)$ have the aforementioned property of being generated by involutive (unitary) reflections. A close look at the case of $G = G(4, 2, 2)$ also illustrates how the Boolean complex $\Delta(G, S)$ can fail to be a simplicial complex. Choose the following generators $S = \{s_1, s_2, s_3\}$:

$$s_1 = \begin{bmatrix} -1 & 0 \\ 0 & 1 \end{bmatrix}, \ s_2 = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}, \ s_3 = \begin{bmatrix} 0 & -i \\ i & 0 \end{bmatrix}.$$

One can check (see [9, Appendix 2]) that the relations among these s_i are generated by

$$s_i^2 = 1, s_1 s_3 s_2 = s_3 s_2 s_1 = s_2 s_1 s_3.$$

These relations have some other consequences, such as

$$(s_i s_j)^4 = 1 \text{ for } i \neq j$$
$$s_i s_j s_i = s_k s_j s_k \text{ whenever } \{i, j, k\} = \{1, 2, 3\}.$$

An Euler characteristic computation then shows that $\Delta(G, S)$ is an orientable surface of genus 4. However, $\Delta(G, S)$ is *not* a simplicial complex, since for example, one can check that the two cosets $s_1 G_{\{s_2, s_3\}} = s_3 s_1 G_{\{s_2, s_3\}}$ and $G_{\{s_1, s_3\}}$ index two vertices which are the endpoints for two different edges, indexed by cosets $s_1 G_{\{s_3\}}$ and $s_3 s_1 G_{\{s_3\}}$.

3.3 Unipotent groups over $\mathbb{F}_2$.

Let G be the unipotent group consisting of all upper unitriangular $n \times n$ matrices over $\mathbb{F}_2$, and let $S = \{s_1, \ldots, s_{n-1}\}$ where s_i has a 1 in the $(i, i+1)$ entry and zeroes elsewhere off the diagonal. It is easy to check that S is a minimal generating set for G consisting of involutions. One can also check that the map $\epsilon : s_i \mapsto -1$ extends to the homomorphism

$$G \xrightarrow{\epsilon} \mathbb{Z}^\times$$
$$(a_{ij})_{i,j=1}^n \mapsto (-1)^{\sum_{i=1}^{n-1} a_{i,i+1}}$$

Therefore $\Delta(G, S)$ is an orientable pseudomanifold by Proposition 2.9.

Biss [2] has shown that all relations among the s_i are generated by the following Coxeter-like relations

$$
\begin{aligned}
s_i^2 &= 1 \\
(s_i s_{i+1})^4 &= 1 \\
(s_i s_j)^2 &= 1 \text{ for } |i - j| > 1,
\end{aligned}
\tag{3.1}
$$

along with the extra relations $(s_i s_{i+1} s_{i+2})^4 = 1$. Consequently Corollary 2.15 implies that $\Delta(G, S)$ is a quotient of the Coxeter complex $\Delta(\hat{W}, \hat{S})$ for the Coxeter system described by the relations (3.1), where one quotients by the normal subgroup K of $\hat{W}$ generated by the elements $(\hat{s}_i \hat{s}_{i+1} \hat{s}_{i+2})^4$.

Example 3.5. Taking the special case where $n = 4$ in the previous discussion, the Coxeter complex $\Delta(\hat{W}, \hat{S})$ is the regular tessellation of the 2-plane by isosceles right triangles, and K acts as a 2-dimensional lattice of translations, yielding a quotient $\Delta(G, S)$ which triangulates a 2-torus, as in Figure 3.1 (b). As in Example 3.1, the fact that one obtains a 2-torus can be predicted independently by an easy Euler characteristic computation.

Example 3.6. We give an example where $\Delta(G, S)$ is non-orientable, but still comprehensible. Let

$$
\begin{aligned}
G &= \mathfrak{S}_4 \\
S &= \{s_0 = (12)(34), s_1 = (23), s_2 = (34)\}.
\end{aligned}
$$

One can easily check that S minimally generates G. By Proposition 2.9, $\Delta(G, S)$ will be a non-orientable surface, and an Euler characteristic computation shows that it is in fact the real projective plane.

Alternatively, one can use Corollary 2.15. Note that the s_i satisfy the Coxeter relations $s_i^2 = (s_0 s_1)^4 = (s_0 s_2)^2 = (s_1 s_2)^3 = 1$ for the (finite) Coxeter system $(\hat{W}, \hat{S})$ of type B_3. One can check that they also satisfy an extra relation: $s_0 s_1 s_0 s_1 s_2 s_1 s_0 s_1 s_2 = 1$. The left-hand side in this relation happens to coincide with the image of the longest element w_0 in $\hat{W}$ under the surjection $\hat{W} \twoheadrightarrow G$, so the kernel K of this surjection must contain the cyclic group of order two generated by w_0 in $\hat{W}$. Hence K must coincide with this cyclic group, since $|W| = 48 = 2|G|$. As $\hat{W}$ is the symmetry group of the regular cube or octahedron, $\Delta(W, S)$ is a 2-sphere isomorphic to the barycentric subdivision of the boundary of the cube or octahedron. The longest element w_0 happens to act in this case as the antipodal map on the 2-sphere $\Delta(\hat{W}, \hat{S})$, and $\Delta(G, S)$ is the triangulation of the real projective plane arising from the antipodal identification.

4   The case of the symmetric group.

Here we examine more closely the case where $G = \mathfrak{S}_n$ considered as a reflection group, and S is a minimal generating set of reflections.

4.1   Trees and forests.

The following proposition is easy and well-known.

Proposition 4.1. *The reflections in $\mathfrak{S}_n$ are the transpositions (ij). A set S of transpositions forms a minimal generating set if and only if the graph on vertex set $[n] := \{1, 2, \ldots, n\}$ having an edge $\{i, j\}$ for each (ij) in S is a spanning tree.*   □

In light of this proposition, we introduce the following bit of notation. Given a spanning tree T on $[n]$, let $\Delta_T := \Delta(\mathfrak{S}_n, S_T)$ where S_T is the corresponding minimal generating set.

Proposition 4.2. *For any spanning tree T on $[n]$, the pair $(\mathfrak{S}_n, S_T)$ satisfies the intersection condition (2.1), and hence Δ_T is a simplicial complex.*

Proof. Given the spanning tree T with edge set corresponding to S_T, for any $J \subset S_T$, one has $G_J = \mathfrak{S}_{B_1} \times \cdots \times \mathfrak{S}_{B_{n-|J|}}$, where $B_1, \ldots, B_{n-|J|}$ are the blocks of the partition of $[n]$ into the vertices of the trees in the subforest of T induced by the edge subset J. Similarly, for each edge s in S_T, there is a corresponding partition of $[n]$ into two blocks B_1^s, B_2^s (the *bond* or *cocircuit* induced by s) such that $G_{S-s} = \mathfrak{S}_{B_1^s} \times \mathfrak{S}_{B_2^s}$. Showing the intersection condition then amounts to showing

$$\mathfrak{S}_{B_1} \times \cdots \times \mathfrak{S}_{B_{n-|J|}} = \bigcap_{s \in S_T - J} \mathfrak{S}_{B_1^s} \times \mathfrak{S}_{B_2^s}$$

or equivalently, in the lattice of partitions of $[n]$ one has

$$\{B_1, \ldots, B_{n-|J|}\} = \bigwedge_{s \in S_T - J} \{B_1^s, B_2^s\}.$$

This is easily shown by induction on $n - |J|$. $\square$

The simplicial complex Δ_T has a useful alternate description. Fix a spanning tree T on $[n]$, so that the vertices of T have a fixed labeling. By a *labelled subforest* (F, w) of T, we mean a subforest F of T along with an assignment w of a subset of $[n]$ to each tree in F, such that a tree having r vertices is assigned a subset of cardinality r, and these subsets disjointly partition $[n]$. Order the labelled subforests by saying $(F, w) \leq (F', w')$ if the vertex set of every tree in F is a union of vertex sets of trees in F', and the corresponding label sets in w are the unions of the label sets in w'.

Proposition 4.3. *For any spanning tree T on $[n]$, the face poset $P(\mathfrak{S}, S_T)$ of Δ_T is isomorphic to the above partial order on labelled subforests of T.*

Proof. A coset wG_J corresponds to a pair (F, w) in which F is the subforest of T induced by the edge set J. Here w indicates how to relabel the vertices of T and hence also how to label the vertex sets of the subtrees in F. It is easy to check that this is a poset isomorphism. $\square$

In fact, the previous description of Δ_T suggests a slightly more general family of simplicial complexes which arise naturally as type-selections of Δ_T. Given a spanning tree T on $[n]$, let a *multiplicity sequence*

$$\mathbf{m} = (m_1, \ldots, m_n) \in \mathbb{N}^n$$

be an assignment of a non-negative integer m_i to each vertex i of T, and call the pair $(T, \mathbf{m})$ a *spanning tree with vertex multiplicities*. For any such pair $(T, \mathbf{m})$, a *labelled subforest* is a pair (F, w) where

- F is a subforest of T,

- w is an assignment of a (possibly empty) subset of $[m]$, where $m := \sum_i m_i$, to each tree in F,

- each tree in F is assigned a subset of cardinality equal to the sum of the m_i as i runs through its vertex set and

- these subsets disjointly partition $[m]$.

Ordering these labelled subforests as before, it is not hard to check that this defines the face poset of a simplicial complex which we will denote $\Delta_{T,\mathbf{m}}$. For example, when $\mathbf{m} = (1, 1, \ldots, 1)$, then $\Delta_{T,\mathbf{m}} = \Delta_T$.

It turns out that every complex $\Delta_{T,\mathbf{m}}$ with $m_i \geq 1$ is a type-selected subcomplex of a complex $\Delta_{\hat{T}}$ for some spanning tree $\hat{T}$ on $[m]$ where $m = \sum_i m_i$. Given $(T, \mathbf{m})$ with $m_i \geq 1$, let $\hat{T}$ be a tree on m vertices and $J \subset S_{\hat{T}}$ a subset of edges such that

- the induced subforest on J has subtrees with m_i vertices for each i,

- the tree obtained from $\hat{T}$ by contracting the edges in J is T (in other words, T is the underlying tree structure connecting the components of the subforest induced by J).

With these definitions, the following proposition is a straightforward translation of the definitions.

Proposition 4.4. *In the above situation,*

$$\Delta_{T,\mathbf{m}} \cong (\Delta_{\hat{T}})_{S_{\hat{T}} - J}.$$

Example 4.5. *Chessboard complexes.*
Let T be an n-vertex *star*, i.e. T has $n - 1$ leaves each connected to the same central vertex v of degree $n - 1$. For $r \in \mathbb{N}$, define a multiplicity sequence $\mathbf{m}_r$ by setting $m_i = 1$ for each leaf vertex i, and $m_v = r$. Then one can easily check that $\Delta_{T,\mathbf{m}_r}$ is isomorphic to the $(n - 1) \times (n + r - 1)$ *chessboard complex* $\Delta_{n-1,n+r-1}$ considered in [1, 8, 15, 17, 26, 34, 35], whose faces correspond to placements of non-attacking rooks on an $(n - 1) \times (n - 1 + r)$ chessboard.

In particular, when T is an n-vertex star,

$$\Delta_T = \Delta_{T,(1,1,\ldots,1)} = \Delta_{T,\mathbf{m}_1} \cong \Delta_{n-1,n}.$$

It was noted in [8, §2] that $\Delta_{n-1,n}$ is a pseudomanifold with singularities lying in codimension at least 3 (but all other chessboard complexes are not pseudomanifolds), in agreement with Proposition 2.9.

We return to this example in the discussion of Example 4.15.

Remark 4.6.
For any pair (G, S) having only involutions in S, the *facet graph* of $\Delta(G, S)$, having vertices indexed by maximal faces and an edge for each pair of maximal faces that share a codimension one face, coincides with the *(undirected) Cayley graph* of G with respect to the generators S. Thus it is possible that the study of $\Delta(G, S)$ and its topology may have a bearing on questions about such Cayley graphs.

In particular, when $G = \mathfrak{S}_n$ and T is a path, so that Δ_T is the Coxeter complex for $\mathfrak{S}_n$, many questions about this Cayley graph have been answered. For other spanning trees T on $[n]$, less is known, although the case where T is the star graph (so that Δ_T is the chessboard complex $\Delta_{n-1,n}$ as in Example 4.5) was considered in [14, §5], and studied more extensively in [23].

4.2 Deletion-contraction and flossing.

For the remainder of the paper, we examine the topology of Δ_T, and particularly the complex representation of $\mathfrak{S}_n$ on its homology $H_\bullet(\Delta_T, \mathbb{C})$. For this purpose, we will make use of standard terminology about the symmetric group and its complex representations, such as can be found in [25, 32]. In what follows, all simplicial chain groups and homology groups are taken with $\mathbb{C}$ coefficients, unless explicitly stated otherwise.

One useful feature of the setting $(G, S) = (\mathfrak{S}_n, S_T)$ is that Proposition 2.18 can be re-interpreted in terms of certain deletion and contraction operations, for which we now introduce notation.

Given a spanning tree with multiplicities $(T, \mathbf{m})$ on $[n]$, and an edge e in the tree with vertex set $e = \{i, j\}$, one can speak of the *contraction T/e* in the usual graph-theoretic sense. In other words, T/e has the same vertex set as T except that i, j have been coalesced into a single vertex ij, and the edges of T/e correspond to the edges of T other than e. Further define $\mathbf{m}/e$ by

$$(\mathbf{m}/e)_k = m_k \text{ for } k \neq i, j$$
$$(\mathbf{m}/e)_{ij} = m_i + m_j$$

so that $(T/e, \mathbf{m}/e)$ is a spanning tree with multiplicity on $[n-1]$. In light of Proposition 4.4, $\Delta_{T/e, \mathbf{m}/e}$ is the type-selected subcomplex $(\Delta_T)_{S_T - \{e\}}$.

When one deletes the edge e from T to obtain the graph $T - e$, it splits into two connected components T' and T'' which (up to isomorphism) are trees on vertex sets $[n']$ and $[n'']$ respectively where $n' + n'' = n$. Let $\mathbf{m}'$ and $\mathbf{m}''$ be the multiplicities in $\mathbf{m}$ restricted to the vertex sets of T' and T'' respectively, so that $(T', \mathbf{m}')$ and $(T'', \mathbf{m}'')$ are spanning trees with multiplicity on $[n']$ and $[n'']$ respectively.

In this case the exact sequence of Proposition 2.18 becomes the following crucial tool.

Proposition 4.7. *Given any spanning tree with multiplicities $(T, \mathbf{m})$ on $[n]$, and any edge e of T, there is a short exact sequence of complexes of $\mathbb{C}[\mathfrak{S}_n]$-modules*

$$0 \to C_\bullet(\Delta_{T/e, \mathbf{m}/e}) \to C_\bullet(\Delta_{T, \mathbf{m}})$$
$$\to (C_\bullet(\Delta_{T', \mathbf{m}'}) \otimes C_\bullet(\Delta_{T'', \mathbf{m}''}))[1] \uparrow_{\mathfrak{S}_{n'} \times \mathfrak{S}_{n''}}^{\mathfrak{S}_n} \to 0.$$

$\square$

There is a particularly useful way to combine two instances of the previous proposition for inductive arguments (used in Subsection 4.3 below), which we will refer to as the *flossing induction*. Say that a pair of leaf vertices ℓ, ℓ' in a tree T *floss* the vertex v if v is the unique branched vertex (i.e. having degree 3 or higher) on the path from ℓ to ℓ' in T.

Proposition 4.8. *In any tree T which is not a path, there exists a triple of vertices $(\ell, \hat{\ell}, v)$ in which $\ell, \hat{\ell}$ are leaves that floss the vertex v.*

Proof. Root the tree T at one of its leaves, so that each edge of T connects a parent vertex to a child vertex, the child being the one further from the root. Also erase the vertices of degree 2 in T, so as to create a homeomorphic (rooted) tree $\bar{T}$ with possibly fewer edges. Because neither T nor $\bar{T}$ is a path, in $\bar{T}$ there will always exist two leaves $\ell, \hat{\ell}$ other than the root which share the same parent vertex v, and these will correspond to a triple $(\ell, \hat{\ell}, v)$ in T as desired. $\square$
Fig. 2: An example of flossing induction: two trees $T, \hat{T}$ related by the two short exact sequences (4.1), (4.2).

When $\ell, \hat{\ell}$ floss v, relabel without loss of generality so that

$$\mathrm{dist}_T(\ell, v) \le \mathrm{dist}_T(\hat{\ell}, v)$$

where $\mathrm{dist}_T(-, -)$ denotes graph-theoretic distance in T.

Definition 4.9. Define $\ell(T)$ to be the number of leaves of a tree T. Define

$$\delta(T) := \min\{\mathrm{dist}_T(\ell, v) : (\ell, \hat{\ell}, v) \text{ such that } \ell, \hat{\ell} \text{ floss } v\},$$

a positive quantity whenever T is not a path, and for convenience define $\delta(T) = 0$ when T is a path.

The flossing induction relates T to a tree $\hat{T}$ which either has fewer vertices, or the same number of vertices but fewer leaves, or the same number of vertices and leaves but with $\delta(\hat{T}) < \delta(T)$; see Figure 4.2 for an example. Let $(\ell, \hat{\ell}, v)$ be a triple such that $\mathrm{dist}_T(\ell, v)$ achieves the minimum $\delta(T)$, and define e to be the first edge on the path from v to ℓ. Then $\hat{T}$ is formed in two steps: one first contracts T along e to create T/e, with a natural multiplicity sequence $\mathbf{m}/e$ assigning multiplicity 2 to the contracted vertex and multiplicity 1 on all other vertices, and then one obtains $\hat{T}$ by "un-contracting" or "stretching" this contracted vertex into a new edge $\hat{e}$ that extends along the path toward ℓ' (equivalently, one can think of $\hat{T}$ as obtained from T/e by subdividing the first edge along the path from the contracted vertex to $\hat{\ell}$).

Note that in this process, one has that $\hat{T}/\hat{e} = T/e$, and hence the spanning tree with multiplicities $(T/e, \mathbf{m}/e)$ fits into two short exact sequences coming from Proposition 4.7,

$$
\begin{aligned}
&0 \to C_\bullet(\Delta_{T/e, \mathbf{m}/e}) \to C_\bullet(\Delta_T) \\
&\quad \to (C_\bullet(\Delta_{T'}) \otimes C_\bullet(\Delta_P))[1] \uparrow_{\mathfrak{S}_{n'} \times \mathfrak{S}_{n''}}^{\mathfrak{S}_n} \to 0
\end{aligned}
\tag{4.1}
$$

$$
\begin{aligned}
&0 \to C_\bullet(\Delta_{\hat{T}/\hat{e}, \mathbf{m}/\hat{e}}) \to C_\bullet(\Delta_{\hat{T}}) \\
&\quad \to (C_\bullet(\Delta_{\hat{T}'}) \otimes C_\bullet(\Delta_{\hat{P}}))[1] \uparrow_{\mathfrak{S}_{\hat{n}'} \times \mathfrak{S}_{\hat{n}''}}^{\mathfrak{S}_n} \to 0
\end{aligned}
\tag{4.2}
$$

which are illustrated schematically in Figure 4.2. Here we denote by $T', P(=T'')$ the two components of $T-e$, and by $\hat{T}', \hat{P}(=\hat{T}'')$, the two components of $\hat{T}-\hat{e}$, emphasizing the fact that the components $P, \hat{P}$ which contain $\ell, \hat{\ell}$, respectively, are paths.

We will say that a proof proceeds *by flossing induction* if it attempts to prove a property of the homology of Δ_T as follows. The base case is when T is a path. When T is not a path, one uses induction simultaneously on the number of vertices in T, the number of leaves $\ell(T)$, and on the quantity $\delta(T)$: one assumes that the property holds for any tree having either

- fewer vertices (such as $T', P, \hat{T}', \hat{P}$), or

- the same number of vertices but fewer leaves (such as $\hat{T}$ if ℓ is adjacent to v in T), or

- the same number of vertices and leaves, but smaller δ value (such as $\hat{T}$ if ℓ is not adjacent to v in T),

and then uses the long exact homology sequences associated with the sequences (4.1) and (4.2), possibly also taking advantage of the fact that $P, \hat{P}$ are paths.

Flossing induction is used in the proofs of Theorem 4.10, 4.11, and 5.3 below.

4.3 Constraints on the homology representations.

The goal of this subsection is to prove several constraints on the irreducible representations of $\mathfrak{S}_n$ which can occur in the homology of Δ_T or $\Delta_{T,\mathbf{m}}$.

Recall that irreducible $\mathbb{C}[\mathfrak{S}_n]$-modules are indexed by partitions λ of n. Let $\mathcal{S}_\lambda$ denote the irreducible indexed by λ. Recall that given a $\mathbb{C}[\mathfrak{S}_n]$-module V, the notation $\langle V, \mathcal{S}_\lambda \rangle$ denotes the multiplicity of $\mathcal{S}_\lambda$ in V.

We first consider the occurrences of *hook representations* $\mathcal{S}_{(r,1^{n-r})}$ in the homology of Δ_T.

Theorem 4.10. *For any spanning tree T on $[n]$, we have*

$$H_{n-2}(\Delta_T) \cong \mathcal{S}_{1^n}.$$

For any hook shape $(r, 1^{n-r})$ and $i < n-2$,

$$\langle H_i(\Delta_T), \mathcal{S}_{(r,1^{n-r})} \rangle = 0.$$

Proof. The first assertion follows from Proposition 2.9. For the rest, we proceed in two steps.

The case $r \leq 2$. Here we argue directly about the occurrences of $\mathcal{S}_{(r,1^{n-r})}$ in the chain groups, and their images under the boundary map.

For $r = 1$, from the description (2.2) of $C_\bullet(\Delta_T)$ and the irreducible decompositions of the coset representations

$$\mathbb{C}[\mathfrak{S}_n / (\mathfrak{S}_{n_1} \times \cdots \times \mathfrak{S}_{n_r})]$$

(sometimes called *Young's rule*), one sees that $\mathcal{S}_{1^n}$ occurs exactly once in $C_\bullet(\Delta_T)$, in degree $n-2$. Thus it must give rise to $(n-2)$-dimensional homology, in agreement with Proposition 2.9.

Similarly $\mathcal{S}_{(2,1^{n-2})}$ occurs

- exactly $n - 1$ times in $C_{n-2}(\Delta_T)$,
- exactly once in each of the summands $\mathbb{C}[G/G_e]$ of $C_{n-3}(\Delta_T)$, as e runs through the $n - 1$ edges of T,
- nowhere else in $C_\bullet(\Delta_T)$.

Based on this, we claim that it would suffice to show the following: there exists

- an ordering $e_1, e_2, \ldots, e_{n-1}$ of the edges of T, and
- for each $i = 1, 2, \ldots, n - 1$ a copy V_i of the irreducible module $\mathcal{S}_{(2,1^{n-2})}$ in $\mathbb{C}[\mathfrak{S}_n]$

with the property that the component maps $\partial^k : \mathbb{C}[G] \to \mathbb{C}[G/G_{e_k}]$ satisfy

- $\partial^k(V_l) = 0$ for $k > l$
- $\partial^k(V_k) \neq 0$.

This would imply, via a triangularity argument and Schur's Lemma, that the $\mathcal{S}_{(2,1^{n-2})}$-isotypic component of C_{n-2} maps under the boundary map isomorphically onto that of C_{n-3}, leaving no $\mathcal{S}_{(2,1^{n-2})}$ in the homology.

To this end, note that if e has endpoints $\{i, j\}$, then $\mathbb{C}[G/G_e]$ is isomorphic as an $\mathbb{C}[\mathfrak{S}_n]$-module to the principal left ideal $\mathbb{C}[\mathfrak{S}_n]\gamma^+_{\{i,j\}}$, where we define for any subset $A \subset [n]$

$$\gamma^+_A := \sum_{w \in \mathfrak{S}_A} w$$

$$\gamma^-_A := \sum_{w \in \mathfrak{S}_A} \epsilon(w)\, w.$$

and ϵ is the sign character. Also the e-component $\mathbb{C}[G] \to \mathbb{C}[G/G_e]$ of the boundary map is (up to a scalar multiple) the map

$$\begin{array}{ccc} \mathbb{C}[\mathfrak{S}_n] & \to & \mathbb{C}[\mathfrak{S}_n]\gamma^+_{\{i,j\}} \\ x & \mapsto & x \cdot \gamma^+_{\{i,j\}}. \end{array}$$

Order the edges $e_1, e_2, \ldots, e_{n-1}$ in such a way that for each i, the edge e_i has a vertex v_i which is a leaf of $T - \{e_1, e_2, \ldots, e_{i-1}\}$. Define V_k to be the principal left ideal $\mathbb{C}[\mathfrak{S}_n]\gamma^+_{\{v_k,v'_k\}}\gamma^-_{[n]-v_k}$, where e_k has endpoints $\{v_k, v'_k\}$.

It follows from the theory of Specht modules that $V_k \cong \mathcal{S}_{(2,1^{n-2})}$. By construction, whenever $k > l$ we have $\{v_k, v'_k\} \subset [n] - v_l$, so that $\gamma^-_{[n]-v_l}\gamma^+_{\{v_k,v'_k\}} = 0$. This implies that

$$\partial^k(V_l) = V_l\gamma^+_{\{v_k,v'_k\}} = \mathbb{C}[\mathfrak{S}_n]\gamma^+_{\{v_l,v'_l\}}\gamma^-_{[n]-v_l}\gamma^+_{\{v_k,v'_k\}} = \mathbb{C}[\mathfrak{S}_n]\gamma^+_{\{v_l,v'_l\}} \cdot 0 = 0$$

for $k > l$. It only remains to show $\partial^k(V_k) \neq 0$, for which it suffices to check that the coefficient of the identity permutation id in $\gamma^+_{\{v_k,v'_k\}}\gamma^-_{[n]-v_k}\gamma^+_{\{v_k,v'_k\}}$ is exactly $+2$, coming from the two terms in the product

$$\begin{array}{ccccc} +\mathrm{id} & \cdot & +\mathrm{id} & \cdot & +\mathrm{id} \\ +(v_k v'_k) & \cdot & +\mathrm{id} & \cdot & +(v_k v'_k). \end{array}$$

This completes the case $r = 2$.

The case $r \geq 3$. We will argue that $\langle H_\bullet(\Delta_T), \mathcal{S}_{(r,1^{n-r})} \rangle = 0$ for $r \geq 3$ via the flossing induction, explained in Subsection 4.2.

First note that if V_i for $i \in \{1,2\}$ are $\mathbb{C}[\mathfrak{S}_{n_i}]$-modules with $n_i \geq 1$ and $n_1 + n_2 = n$ having the property that $\langle V_i, \mathcal{S}_{(r,1^{n_i-r})} \rangle = 0$ for $r \geq 2$, then the *Littlewood-Richardson rule* shows that

$$\langle (V_1 \otimes V_2) \uparrow_{\mathfrak{S}_{n_1} \times \mathfrak{S}_{n_2}}^{\mathfrak{S}_n}, \mathcal{S}_{(r,1^{n-r})} \rangle = 0 \text{ for } r \geq 3.$$

(In fact, we will only need this in the special case of the Littlewood-Richardson rule known as *Pieri's formula*, where V_2 is the sign representation $\mathcal{S}_{1^{n_2}}$; this is due to the fact that $P, \hat{P}$ are paths, and hence have only the sign representation occurring in the homology of the Coxeter complexes $\Delta_P, \Delta_{\hat{P}}$).

Since $T', P, \hat{T}', \hat{P}$ all have fewer vertices than T, induction applies to them, and then the Künneth formula along with the previous fact shows that the homology of the third term in both short exact sequences (4.1) and (4.2) contains no occurrence of $\mathcal{S}_{(r,1^{n-r})}$ for $r \geq 3$. On the other hand, induction also applies to $\hat{T}$, because it has its shortest distance from a leaf to a branched vertex shorter than in T or else the distance was 1 and $\hat{T}$ has fewer leaves than T. So the homology of the middle term in (4.2) has no occurrences of $\mathcal{S}_{(r,1^{n-r})}$ for $r \geq 2$. This implies by the long exact sequence in homology that the homology of the first term in (4.2) contains no occurrences of $\mathcal{S}_{(r,1^{n-r})}$ for $r \geq 3$. But since $\hat{T}/\hat{e} = T/e$ implies that this is the same as the homology of the first term in (4.1), we can conclude that the homology of the middle term in (4.1) has this same property, as desired. $\square$

A similar flossing induction argument gives a bound on the length of the longest row of λ for any $\mathcal{S}_\lambda$ which occurs in the homology of Δ_T.

Theorem 4.11. *For any spanning tree T on $[n]$ with $\ell(T)$ leaves, and any partition λ of n*

$$\langle H_\bullet(\Delta_T), \mathcal{S}_\lambda \rangle = 0 \quad \text{unless} \quad \lambda_1 > \ell(T) - 1.$$

Proof. We use flossing induction, as in the last proof, taking advantage of the fact that $P, \hat{P}$ are paths, so that their homology only contains the irreducible representations $\mathcal{S}_{1^{n''}}, \mathcal{S}_{1^{\hat{n}''}}$ respectively. Note that *Pieri's formula* implies that for any partition μ of n' and λ a partition of n, one has

$$\langle (\mathcal{S}_\mu \otimes \mathcal{S}_{1^{n''}}) \uparrow_{\mathfrak{S}_{n'} \times \mathfrak{S}_{n''}}^{\mathfrak{S}_n}, \mathcal{S}_\lambda \rangle = 0 \text{ if } \lambda_1 > \mu_1 + 1.$$

The other crucial facts are that

$$\ell(T') = \ell(T) - 1$$
$$\ell(\hat{T}') = \ell(\hat{T}) - 1$$
$$\ell(\hat{T}) \leq \ell(T).$$

$\square$

We conjecture that the number of leaves $\ell(T)$ also gives rise to a (loose) lower bound on the connectivity of $\Delta_{T,\mathbf{m}}$. Recall that a topological space X is said to be *k-connected* if its homotopy groups $\pi_i(X)$ vanish for $i \leq k$.

Conjecture 4.12. *For any spanning tree with multiplicities* $(T, \mathbf{m})$ *on* $[n]$ *with* $\ell(T)$ *leaves, the complex* $\Delta_{T,\mathbf{m}}$ *is* $(n - 1 - \ell(T))$-*connected.*

This conjecture is well-known and tight for $\ell(T) = 2$; see Example 4.14 below. It also turns out to hold when $\mathbf{m} = (1, 1, \ldots, 1)$ for $\ell(T) = 3$ (see Appendix 7), and is tight in this case by Theorem 5.3. However, see the discussion of chessboard complexes in Example 4.15 below as an illustration of the looseness of this conjectural connectivity bound in general.

Some recent ideas of P. Hersh [19] regarding a notion of *weak ordering* on $(n - \ell(T))$-faces of $\Delta_{T,\mathbf{m}}$ may lead to a stronger assertion than Conjecture 4.12, namely that the $(n - \ell(T))$-skeleton is shellable. Similar results were proven by Ziegler [34], Shareshian and Wachs, [26], and Athanasiadis [1], for chessboard and matching complexes.

Lastly we mention a somewhat trivial constraint on the homology representations of $\Delta_{T,\mathbf{m}}$ which ignores the tree structure T. Given two partitions λ and μ of the same number, say that λ *dominates* μ, written $\lambda \rhd \mu$, if $\sum_{i=1}^{k} \lambda_i \geq \sum_{i=1}^{k} \mu_i$ for all k.

Proposition 4.13. *Assume* $m_1 \geq \cdots \geq m_n$ *by re-indexing, if necessary.*
Then $\langle H_\bullet(\Delta_{T,\mathbf{m}}), \mathcal{S}_\lambda \rangle \neq 0$ *implies* $\lambda \rhd \mathbf{m}$.

Proof. The same constraint turns out to hold on the chain level. One checks that $C_\bullet(\Delta_{T,\mathbf{m}})$ is a direct sum of $\mathbb{C}[\mathfrak{S}_m]$-modules of the form $\mathbb{C}[\mathfrak{S}_m/(\mathfrak{S}_{m'_1} \times \cdots \times \mathfrak{S}_{m'_{n'}})]$ where $\mathbf{m}' = (m'_1, \ldots, m'_{n'})$ is obtained from $\mathbf{m}$ by merging parts, and therefore $\mathbf{m}' \rhd \mathbf{m}$. On the other hand, it is well-known from Young's rule that

$$\langle \mathbb{C}[\mathfrak{S}_m/(\mathfrak{S}_{m'_1} \times \cdots \times \mathfrak{S}_{m'_{n'}})], \mathcal{S}_\lambda \rangle \neq 0$$

implies $\lambda \rhd \mathbf{m}'$. Hence $\lambda \rhd \mathbf{m}' \rhd \mathbf{m}$. $\qquad\square$

4.4 Some examples.

Example 4.14. *Rank-selections of Boolean algebras.*
In the case when $\ell(T) = 2$, so that T is a path with n vertices, the complex $\Delta_{T,\mathbf{m}}$ is a type-selected subcomplex of the Coxeter complex for $\mathfrak{S}_m$ where $m = \sum_i m_i$. Equivalently, it is the order complex for a rank-selection of the Boolean algebra $2^{[m]}$. Specifically, if the vertices along the path T are labelled $1, 2, \ldots, n$ in order, then $\Delta_{T,\mathbf{m}}$ corresponds to selecting $2^{[m]}$ at the rank

$$D_{\mathbf{m}} := \{m_1, m_1 + m_2, \ldots, m_1 + m_2 + \cdots + m_{n-1}\}.$$

The Coxeter complex is *shellable*, a property which is automatically inherited by all of its type-selected subcomplexes (see e.g. [3, §11]). Hence in this case $\Delta_{T,\mathbf{m}}$ is homotopy equivalent to a wedge of $(n - 2)$-spheres, which is $(n - 3)$-connected, in agreement with Conjecture 4.12.

The homology is also well-known as an $\mathbb{C}[\mathfrak{S}_m]$-module (see [33, Theorem 4.3]): the multiplicity of $\mathcal{S}_\lambda$ in $H_{n-3}(\Delta_{T,\mathbf{m}})$ is the number of standard Young tableaux of shape λ whose *descent set* is exactly $D_{\mathbf{m}}$.

We should point out that this entire discussion is known to generalize to Coxeter complexes associated to an arbitrary finite Coxeter system (W, S); see [6, Remark 6.7]. The Coxeter complex $\Delta(W, S)$ and all of its type-selections $\Delta(W, S)_J$ are shellable, and their associated homology representations can be expressed in terms of the *Kazhdan-Lusztig cell representations* corresponding to *left cells* having a fixed *descent set* (using an appropriate definition of descents for Coxeter group elements).

Example 4.15. *Chessboard complexes revisited.*

Recall from Example 4.5 that when T is an n-vertex star and $\mathbf{m}$ assigns r to the central vertex and 1 to the remaining vertices, $\Delta_{T,\mathbf{m}}$ is the chessboard complex $\Delta_{n-1,n+r-1}$. In [8] it was shown that $\Delta_{m,n}$ is $\nu - 2$-connected, where we assume $m \le n$ and

$$\nu = \min\left(m, \left\lfloor \frac{m+n+1}{3} \right\rfloor\right).$$

It was also conjectured there (and recently proven by Shareshian and Wachs [26]) that this connectivity bound is tight. This shows that the above conjecture on the connectivity of $\Delta_{T,\mathbf{m}}$ for T a star and $\mathbf{m}$ as above is very far from tight: these known results show that in this chessboard case, $\Delta_{T,\mathbf{m}}$ is roughly $\frac{2n+r-2}{3}$-connected, while Conjecture 4.12 would only assert that it is 0-connected (i.e. connected) .

The chessboard examples also illustrate how far the homology with complex coefficients can deviate from the integral homology for $\Delta_{T,\mathbf{m}}$. The homology with complex coefficients of $\Delta_{m,n}$ was described completely by Friedman and Hanlon [15], even as a $\mathbb{C}[\mathfrak{S}_m \times \mathfrak{S}_n]$-module. For example, if T is a star, then using their results for $\Delta_{n-1,n}$ one can deduce that $H_i(\Delta_T, \mathbb{C})$ will start to vanish for i roughly below dimension $n - \sqrt{n}$, while the results of [8, 26] show that the $H_i(\Delta_T, \mathbb{Z})$ will only start to vanish for i roughly below dimension $\frac{2n}{3}$.

5   The case of a single branch vertex.

In this section, we examine more closely the simplicial complexes Δ_T (and more generally, $\Delta_{T,\mathbf{m}}$) introduced in the previous section, in the case where T is a tree having at most one *branch* vertex, i.e. at most one vertex of degree 3 or higher. Note that this class encompasses both Examples 4.14 and 4.15.

5.1   A general lower bound.

We begin with a companion lower bound for the upper bound on λ_1 given in Theorem 4.11. Note that this bound is sensitive to the dimension in which the homology occurs.

Theorem 5.1. *Assume T is a spanning tree on $[n]$ having at most one branch vertex v, and that $\mathbf{m}$ achieves its maximum value at m_v. Then*

$$\langle H_i(\Delta_{T,\mathbf{m}}), \mathcal{S}_\lambda \rangle = 0 \;\; \text{if} \;\; \lambda_1 < m_v + n - 2 - i.$$

Remark 5.2. The assumptions that T has only one branch vertex v and that m_v achieves the maximum value in $\mathbf{m}$ turn out to be necessary here. The spanning tree T on $[n] = [8]$ with edge set

$$\{12, 13, 14, 45, 56, 67, 68\}$$

has more than one branch vertex, and computer calculations show that $\langle H_4(\Delta_T), \mathcal{S}_{(2,2,2,2)} \rangle = 1$, violating the above inequality. The spanning tree T on $[n] = [5]$ having edge set $\{12, 23, 34, 35\}$ has one branch vertex $v = 3$, and if we take $\mathbf{m} = (2, 1, 1, 1, 1)$ so that $m_3 = 1$ is not the maximum value in $\mathbf{m}$, then computer calculations show $\langle H_2(\Delta_{T,\mathbf{m}}), \mathcal{S}_{(2,2,2)} \rangle = 1$, violating the above inequality.

Note also that the hypotheses of the theorem are satisfied by the pairs $(T, \mathbf{m})$ for which $\Delta_{T,\mathbf{m}}$ is a chessboard complex (see Example 4.5).

Proof. We use induction on the number of edges in T and utilize Proposition 4.7, choosing e to be any edge of T incident to the branch vertex v. Note that since $\lambda_1 < m_v + n - 2 - i$ and $(\mathbf{m}/e)_v \geq m_v + 1$, we have $\lambda_1 < (\mathbf{m}/e)_v + (n-1) - 2 - i$. Therefore induction applies to show $\langle H_i(\Delta_{T/e, \mathbf{m}/e}), \mathcal{S}_\lambda \rangle = 0$ so $\mathcal{S}_\lambda$ does not occur in the i-dimensional homology of the first term of the short exact sequence of Proposition 4.7.

We wish to show that $\mathcal{S}_\lambda$ also does not occur in the i-dimensional homology of the third term of this short exact sequence, so that the desired vanishing would follow from the associated long exact sequence in homology. Without loss of generality, we may assume that T' is the subtree containing v, so that T'' is a path. Induction applies to T', so that $\langle H_{i'}(\Delta_{T', \mathbf{m}'}), \mathcal{S}_{\mu'} \rangle \neq 0$ implies $\mu_1' \geq m_v + n' - 2 - i'$. Also note that Example 4.14 implies $\Delta(T'')$ only has homology in dimension $n'' - 2$. Therefore by the Künneth formula, $\mathcal{S}_\lambda$ can only occur in the i-dimensional homology of the third term if it occurs in the decomposition of some tensor product $\mathcal{S}_{\mu'} \otimes \mathcal{S}_{\mu''}$ into irreducibles where $n' + n'' = n$, $\mu' \vdash n'$, $\mu'' \vdash n''$ and one has $\mu_1' \geq m_v + n' - 2 - i'$ for some i' satisfying $i' + (n'' - 2) = i - 2$. On the other hand, the Littlewood-Richardson rule for decomposing this tensor product easily implies that $\lambda_1 \geq \mu_1'$. Putting all of these inequalities and equalities together gives $\lambda_1 \geq m_v + n - 2 - i$, a contradiction. $\qquad\square$

5.2   The case of three leaves.

The case $\ell(T) = 2$ was discussed in Example 4.14, and using some of our results constraining the homology, we can now deal with the case where $\ell(T) = 3$ with all multiplicities 1, i.e. $\mathbf{m} = (1, 1, \ldots, 1)$. Let $T_{a,b,c}$ be the spanning tree on $[n]$ for $n = a + b + c + 1$ which has a central vertex v of degree 3, and three "arms" consisting of a, b and c other vertices respectively. We assume without loss of generality that $a \geq b \geq c \geq 1$.

We introduce the following convenience for describing the homology representations of $\Delta_{T_{a,b,c}}$. For two pairs $(p, q), (r, s)$ of positive integers satisfying $p + q = r + s = n$ and $p > \max(r, s) \geq \min(r, s) > q$, define a (virtual) $\mathbb{C}[\mathfrak{S}_n]$-module by the equation

$$V_{(p,q),(r,s)} \oplus \left(\mathcal{S}_{1^p} \otimes \mathcal{S}_{1^q} \uparrow^{\mathfrak{S}_n}_{\mathfrak{S}_p \times \mathfrak{S}_q} \right) \cong \mathcal{S}_{1^r} \otimes \mathcal{S}_{1^s} \uparrow^{\mathfrak{S}_n}_{\mathfrak{S}_r \times \mathfrak{S}_s}$$

which actually turns out to define a genuine (not virtual) representation

$$V_{(p,q),(r,s)} \cong \bigoplus_{k=q+1}^{\min(r,s)} \mathcal{S}_{(2^k, 1^{n-2k})}. \tag{5.1}$$

Theorem 5.3. *Let $a \geq b \geq c \geq 1$ and $n = a + b + c + 1$. Then $\Delta_{T_{a,b,c}}$ has all of its (reduced) integral homology concentrated in dimensions $n - 2$ and $n - 3$, and no torsion.*

Furthermore, the homology with $\mathbb{C}$ coefficients has the following description as an $\mathbb{C}[\mathfrak{S}_n]$-module:

$$H_i(\Delta_{T_{a,b,c}}) \cong \begin{cases} \mathcal{S}_{1^n} & \text{if } i = n - 2 \\ \bigoplus_{c_1, c_2 \geq 1, \ c_1 + c_2 = c + 1} V_{(a+b+c_1, c_2), (b+c_2, a+c_1)} & \text{if } i = n - 3 \end{cases}$$

Remark 5.4. Note that using this theorem, one could easily write down a formula which is piecewise-linear in k for the multiplicities

$$c_k := \langle H_{n-3}(\Delta_{T_{a,b,c}}), \mathcal{S}_{(2^k, 1^{n-2k})} \rangle.$$

However the presence of the $\min(r, s)$ in the formula (5.1) for $V_{(p,q),(r,s)}$ would make this somewhat clumsy.

Remark 5.5. Note also that the theorem is consistent with the constraints from Theorems 4.10, 4.11 and 5.1. In fact, these results would suffice to imply all of the assertions about vanishing homology in the theorem, except for the lack of torsion.

Proof. Since $\Delta_{T_{a,b,c}}$ has dimension $n-2$, Theorem 7.3 below implies the result about homology concentration. It also implies that there is no torsion in $H_i(\Delta_{T_{a,b,c}}, \mathbb{Z})$: the only non-vanishing homology groups are the top two, and Proposition 2.9 implies that $\Delta_{T_{a,b,c}}$ is an orientable pseudomanifold, which never has torsion in its top two homology groups (see e.g. [29, p. 206, Exerc. 4.E.2]).

We know from Proposition 2.9 that the assertion of the theorem for $i = n - 2$ is correct, and that this top homology gives the only occurrence of $\mathcal{S}_{1^n}$. Thus only the homology in the single dimension $n - 3$ is unknown, and there can be no two occurrences of the same irreducible module in two different homology groups. It therefore suffices to compute the *(virtual-)*$\mathbb{C}[\mathfrak{S}_n]$*-module Euler characteristic* (or *Lefschetz character*) which is the formal sum of modules

$$\chi(T_{a,b,c}) := \sum_{i \geq 0} (-1)^i \langle H_i(\Delta_{T_{a,b,c}}), \mathcal{S}_\lambda \rangle \, \mathcal{S}_\lambda$$

For this we again use the two exact sequences (4.1) and (4.2), choosing the edge e on $T := T_{a,b,c}$ to be the edge containing the central vertex v and lying on the arm having c vertices, and choosing the edge $\hat{e}$ on $\hat{T} := T_{a+1,b,c-1}$ to be the edge containing v which lies on the arm having $a + 1$ vertices (Note: this is again an example of the flossing induction). Let $\mathbf{m}$ and $\hat{\mathbf{m}}$ be the multiplicity sequences of all ones on T and $\hat{T}$ respectively so that $(T, \mathbf{m})/e = (\hat{T}, \hat{\mathbf{m}})/\hat{e}$. If we let P_r denote a path having r vertices, these two exact sequences become:

$$0 \to C_\bullet(\Delta_{T/e,\mathbf{m}/e}) \to C_\bullet(\Delta_{T_{a,b,c}})$$
$$\to (C_\bullet(\Delta_{P_c}) \otimes C_\bullet(\Delta_{P_{a+b+1}}))[1] \uparrow_{\mathfrak{S}_c \times \mathfrak{S}_{a+b+1}}^{\mathfrak{S}_n} \to 0$$

$$\text{(5.2)}$$

$$0 \to C_\bullet(\Delta_{\hat{T}/\hat{e},\hat{\mathbf{m}}/\hat{e}}) \to C_\bullet(\Delta_{T_{a+1,b,c-1}})$$
$$\to (C_\bullet(\Delta_{P_{a+1}}) \otimes C_\bullet(\Delta_{P_{b+c+1}}))[1] \uparrow_{\mathfrak{S}_{a+1} \times \mathfrak{S}_{b+c+1}}^{\mathfrak{S}_n} \to 0$$

Since Euler characteristics are additive on short exact sequences and multiplicative on tensor products, one concludes that

$$\chi(T_{a,b,c}) = \chi(T/e, \mathbf{m}/e) - \chi(\Delta_{P_c}) \otimes \chi(\Delta_{P_{a+b+1}})$$
$$\chi(T_{a+1,b,c-1}) = \chi(\hat{T}/\hat{e}, \mathbf{m}/\hat{e}) - \chi(\Delta_{P_{a+1}}) \otimes \chi(\Delta_{P_{b+c+1}}).$$

where the symbols $\otimes$ on the right-hand side should be interpreted as the induction product on virtual characters. Since Δ_{P_r} is the Coxeter complex for $\mathfrak{S}_r$ whose homology vanishes except for $\mathcal{S}_{1^r}$ in the top dimension, one concludes that

$$\chi(T_{a,b,c}) - \chi(T_{a+1,b,c-1})$$
$$= \mathcal{S}_{1^{b+c}} \otimes \mathcal{S}_{1^{a+1}} \uparrow_{\mathfrak{S}_{b+c} \times \mathfrak{S}_{a+1}}^{\mathfrak{S}_n} - \mathcal{S}_{1^{a+b+1}} \otimes \mathcal{S}_{1^c} \uparrow_{\mathfrak{S}_{a+b+1} \times \mathfrak{S}_c}^{\mathfrak{S}_n}$$
$$= -V_{(a+b+1,c),(b+c,a+1)}$$

By induction on c, and using the fact that $T_{a,b,0} = P_{a+b+1}$ for the base case, one obtains

$$\chi_{T_{a,b,c}} = (-1)^{n-2} \left(\mathcal{S}_{1^n} - \sum_{c_1,c_2 \geq 1, c_1+c_2=c+1} V_{(a+b+c_1,c_2),(b+c_2,a+c_1)} \right)$$

as desired.   □

6   Remarks and questions.

We begin by asking: What is the correct (tight) version of Conjecture 4.12? Can one prove such a result via *shellability* or *vertex-decomposability* of some skeleton of $\Delta_{T,\mathbf{m}}$, as in [1, 34]?

A different question deals with how the two extremes of trees from Examples 4.5 and 4.14 bound the homology of Δ_T for an arbitrary spanning tree T on $[n]$. Let P_n denote the path with n vertices, and Star_n the star graph on n vertices. Since for any tree T, the complex Δ_T is an orientable pseudomanifold carrying the sign representation of $\mathfrak{S}_n$ on its top homology (Proposition 2.9), the homology of the Coxeter complex for $\mathfrak{S}_n$ (that is, Δ_{P_n}) trivially gives a lower bound for the multiplicities of irreducible $\mathfrak{S}_n$-representations in any homology group $H.(\Delta_T, \mathbb{C})$. We speculate that the chessboard complex $\Delta_{n-1,n}$ (that is Δ_{Star_n}) provides a companion upper bound:

Question 6.1. Is it true that for every irreducible $\mathfrak{S}_n$-representation $\mathcal{S}_\lambda$, and every spanning tree T on $[n]$, one has

$$\langle \tilde{H}_i(\Delta_{P_n}, \mathbb{C}), \mathcal{S}_\lambda \rangle \leq \langle \tilde{H}_i(\Delta_T, \mathbb{C}), \mathcal{S}_\lambda \rangle \leq \langle \tilde{H}_i(\Delta_{\mathrm{Star}_n}, \mathbb{C}), \mathcal{S}_\lambda \rangle?$$

One can check using Theorem 5.3 and the results of [15] that the answer is affirmative when T has at most 3 leaves, but we have not checked it extensively in other cases. One could also ask more generally whether there exists a partial ordering $\leq$ on all spanning trees on $[n]$, roughly from "less branched" to "more branched", so that paths are at the bottom and stars are at the top, with the property that $T \leq T'$ implies

$$\langle \tilde{H}_i(\Delta_T, \mathbb{C}), \mathcal{S}_\lambda \rangle \leq \langle \tilde{H}_i(\Delta_{T'}, \mathbb{C}), \mathcal{S}_\lambda \rangle.$$

Lastly, we remark that chessboard complexes have the unexpected property that the combinatorial Laplacians defined from their simplicial boundary maps have only integer spectra [15], but unfortunately, the same property is not shared by Δ_T in general. This fails, in fact, even when T is a path P_n for $n \geq 4$.

7   Appendix: A special case of the connectivity Conjecture 4.12.

Our goal here is to use nerve-type arguments as in [8] to prove Theorem 7.3 below. This result confirms Conjecture 4.12 in a very special case needed for the assertions about torsion-free homology in Theorem 5.3: the case where T has 3 leaves, and the multiplicity sequence $\mathbf{m}$ assigns 1 to all vertices except possibly for the unique vertex v of degree 3. It is due to the different flavor of the arguments in this proof, and our hope that the conjecture (or a tighter connectivity bound) will eventually be proven, that we have relegated this discussion to an appendix.

Let $\Delta_{a_1,\ldots,a_k}^r$ denote the complex $\Delta_{T,\mathbf{m}}$ when T has

- $\ell(T) = k$,

- a central vertex v of degree k,

- k *arms* consisting of a_i other vertices each,

- $n := 1 + \sum a_i$ vertices total,

- **m** assigning multiplicity 1 to all vertices except v,

- $m_v = r$.

For example $\Delta^1_{a,b,c}$ is what was previously called $\Delta_{T_{a,b,c}}$. We also allow for the possibility that $r < 0$, even though this was not originally allowed in the definition of $\Delta_{T,\mathbf{m}}$; one can check that $\Delta^r_{a_1,\ldots,a_k}$ is a well-defined, non-empty simplicial complex as long as $m := r + \sum_i a_i \geq 0$. Our goal will be to describe the homotopy type of $\Delta^r_{a_1,a_2}$ for r an arbitrary integer, and the connectivity of $\Delta^r_{a_1,a_2,a_3}$ for $r \geq 1$.

We begin with $\Delta^r_{a_1,a_2}$. Of course, here the tree T is unbranched, and hence Example 4.14 applies as long as $r \geq 1$. But since we are allowing r to be an arbitrary integer, more needs to be said to determine the homotopy type of $\Delta^r_{a_1,a_2}$ in general.

Lemma 7.1. *For $a_1 \geq a_2 \geq 0$ and $r \in \mathbb{Z}$, let*

$$m = a_1 + a_2 + r$$
$$n = a_1 + a_2 + 1.$$

Then the homotopy or homeomorphism type of $\Delta^r_{a_1,a_2}$ is as follows.

For $r \geq 1$, one has that $\Delta^r_{a_1,a_2}$ is a type-selected subcomplex of the Coxeter complex of type A_{m-1}, and hence homotopy equivalent to a wedge of $(n-2)$-spheres.

Otherwise, $\Delta^r_{a_1,a_2}$ is

$$
\begin{cases}
\text{a homotopy } (m-2)\text{-sphere} & \text{if } 0 \leq -r < a_2 \\
\text{contractible} & \text{if } a_2 \leq -r < a_1 \\
\text{a type } A_m \text{ Coxeter complex} & \text{if } a_1 \leq -r < n \\
\text{empty} & \text{if } n \leq -r.
\end{cases}
$$

Proof. The assertions for $r \geq 1$ and for $n \leq -r$ follow from the previous discussion.

For r in the range $0 \leq -r < a_2$, we use a nerve argument. Cover $\Delta^r_{a_1,a_2}$ by the stars of the vertices v_i for $i = 1, 2, \ldots, m$, where v_i corresponds to the labelled subforest of the path on n vertices which has a singleton on the end-vertex of the a_1-vertex branch labelled by the singleton subset $\{i\}$ and the remaining path of $n-1$ vertices labelled by the set $[m] - \{i\}$. It is easy to check that this indeed covers $\Delta^r_{a_1,a_2}$, using the fact that $a_1 + r \geq 1$. One can also check that for any $t < m$, the intersection of the stars of $v_{i_1}, \ldots, v_{i_t}$ will have a cone vertex. Specifically, this cone vertex corresponds to the labelled subforest with $s = t$ if $t \leq a_1$ and $s = t - r + 1$ otherwise, partitioning the path into the s vertices furthest toward the a_1-vertex branch, labelled by the set $\{i_1, \ldots, i_t\}$, and the $n - s$ remaining vertices, labelled by the complementary set $[m] - \{i_1, \ldots, i_t\}$. On the other hand, for $t = m$, this labelled subforest is no longer a vertex as it does not partition the path into two sets (the second set has cardinality $n - t + r - 1 = n - m + r - 1 = 0$), and in fact the intersection of all of the stars of the v_i is the empty face. Hence by the usual nerve lemma (see [3, (10.7)], or the limiting case $k = \infty$ in the Lemma 7.2 below), $\Delta^r_{a_1,a_2}$ is homotopy equivalent to the nerve of this covering, which is the boundary of an $(m-1)$-dimensional simplex, so an $(m-2)$-sphere.

The same nerve argument works for r in the range $a_2 \leq -r < a_1$. The only difference is that now for $t = m \leq a_1$ the intersection will no longer be the empty face, and will again have a cone vertex corresponding to the labelled subforest described as the first case in previous paragraph. Hence the usual nerve lemma implies that $\Delta^r_{a_1,a_2}$ is contractible in this situation.

If $a_1 \leq -r < n = a_1 + a_2 + 1$, we repeatedly use the following isomorphism of simplicial complexes:

$$\Delta^r_{a_1,a_2} \cong \Delta^{r+1}_{a_1,a_2-1} \text{ if } a_1 + r < 0. \tag{7.1}$$

This isomorphism (7.1) is a special case of the inclusion in the cofibration sequence of Remark 4.7, in which e is one of the two edges incident to the vertex v, namely the edge pointing toward the branch having a_2 vertices. Here the inclusion is also surjective (and hence an isomorphism) because the assumption that $a_1 + r < 0$ implies every non-trivial labelled subforest must use e in one of its subtrees. We obtain

$$\Delta^r_{a_1,a_2} \cong \Delta^{-a_1}_{a_1,m} \cong \Delta^{-m}_{m,m}$$

by applying the isomorphism (7.1) first $-(r+a_1)$ times to lower the a_2 in the subscript, and then $-(r+a_2)$ times to lower the a_1 in the subscript.

It only remains to describe an isomorphism from $\Delta^{-m}_{m,m}$ to the Coxeter complex of type A_m. Given a typical labelled subforest corresponding to a face of $\Delta^{-m}_{m,m}$, its subtrees are labelled by sets which give an ordered decomposition of $[m]$, i.e. a sequence of sets $B_1, \ldots, B_r$ with $[m] = \amalg_i B_i$, where it is possible that the set B_{i_0} labeling the unique subtree containing vertex v is the empty set. Replacing B_{i_0} by $B_{i_0} \cup \{m+1\}$ gives an ordered decomposition of $[m+1]$ into non-empty sets, which labels a typical face in the Coxeter complex of type A_m. One can easily check that this is the desired isomorphism.   □

For the case of $\Delta^r_{a_1,a_2,a_3}$, we use a connectivity nerve lemma from [8].

Lemma 7.2. *[8, Lemma 1.2] Let Δ be a simplicial complex covered by a family $\{\Delta_i\}_{i=1}^s$. Suppose that every non-empty intersection $\bigcap_{j=1}^t \Delta_{i_j}$ is $(k-t+1)$-connected for $t \geq 1$. Then Δ is k-connected if and only if the nerve of the covering $\{\Delta_i\}_{i=1}^s$ is k-connected.*   □

Theorem 7.3. *Given $a_1, a_2, a_3 \geq 0$, let $n = a_1 + a_2 + a_3 + 1$.*
If $r \geq 1$, the complex $\Delta^r_{a_1,a_2,a_3}$ is $(n-4)$-connected. In particular, $\Delta_{T_{a,b,c}}$ is $(n-4)$-connected.

Remark 7.4. Note that this agrees with Conjecture 4.12 in this case, since $\ell(T) = 3$ here.

Remark 7.5. Although $\Delta^r_{a_1,a_2,a_3}$ is a well-defined simplicial complex even for r negative, some lower bound on r is necessary for the conclusion of the theorem. For example, the complex $\Delta^{-2}_{1,1,1}$ is isomorphic to the 1×3 chessboard complex, and has $n = 4$, but is disconnected, i.e. not 0-connected.

Proof. We use a nerve argument as in the proof of the previous theorem, but applying Lemma 7.2. Cover $\Delta^r_{a_1,a_2,a_3}$ by the stars of the vertices v_i for $i = 1, 2, \ldots, m$, where v_i corresponds to the labelled subforest which has a singleton on the end-vertex of the a_1-vertex branch labelled by the singleton subset $\{i\}$ and the remaining tree of $n - 1$ vertices labelled by the set $[m] - \{i\}$. As before, these stars do indeed cover $\Delta^r_{a_1,a_2,a_3}$, using the fact that $a_1 + r \geq 1$. Also as before, one can check that for any $t \leq \min(a_1, m-1)$, the intersection of the stars of $v_{i_1}, \ldots, v_{i_t}$ will have a cone vertex with a similar description to the one in the previous proof: the branch with a_1 vertices has an end subtree labelled by the set $\{i_1, \ldots, i_t\}$, and the remaining vertices form a subtree labelled by the complementary set $[m] - \{i_1, \ldots, i_t\}$.

For t in the range $a_1 < t < m$, one can check that the intersection of the stars of $v_{i_1}, \ldots, v_{i_t}$ is isomorphic to $\Delta_{a_2,a_3}^{r+a_1-t}$. By checking various cases using Lemma 7.1, one concludes that $\Delta_{a_2,a_3}^{r+a_1-t}$ is always at least $(n-3-t)$-connected for t in this range.

Finally, if $t = m$, this intersection of stars is the empty face. This means that the nerve of this covering is the boundary of an $(m-1)$-simplex, and hence $(m-3)$-connected. Since $r \geq 1$ implies $m - 3 \geq n - 3$, the nerve is $(n-3)$-connected, and we can apply Lemma 7.2 to conclude that Δ_{a_1,a_2,a_3}^r is $(n-3)$-connected. $\qquad\square$
