We consider random paths on a square lattice which take a left or a right turn at every vertex. The possible turns are taken with equal probability, except at a vertex which has been visited before. In such case the vertex is left via the unused edge. When the initial edge is reached the path is considered completed. We also consider families of such paths which together cover every edge of the lattice once and visit every vertex twice. Because these paths may touch but not intersect each other and themselves, we call them osculating walks. The ensemble of such families is also known as the dense $O(n = 1)$ model. We consider in particular such paths in a cylindrical geometry, with the cylindrical axis parallel with one of the lattice directions. We formulate a conjecture for the probability that a face of the lattice is surrounded by m distinct osculating paths. For even system sizes we give a conjecture for the probability that a path winds round the cylinder. For odd system sizes we conjecture the probability that a point is visited by a path spanning the infinite length of the cylinder. Finally we conjecture an expression for the asymptotics of a binomial determinant

Keywords: Random walks, $O(n)$ loop model

1 Introduction

In this article we present conjectures on the probability distribution of random paths on an $L \times \infty$ square lattice with periodic boundary conditions. The geometry of the lattice is thus a cylinder with circumference L . When L is even (assumed tacitly) the paths are closed loops with probability one. When L is odd (always stated explicitly) there is an infinite path spanning the length of the cylinder.

The paths are allowed to have vertices in common but can not intersect. At each vertex the paths must turn, either to the left or to the right. These two possibilities are assigned equal probability, except when the vertex has been visited before. In that case the path leaves the vertex via the unused edge. This rule prevents (self) intersection of paths. When a path reaches its initial edge it is considered completed. We call paths of this type osculating walks. Osculating lattice paths were considered in [3]. The conjectures

Fig. 1: The two vertices of the dense O(1) loop model

are obtained from the ground state of the dense O(1) loop model. The dense O(n) loop model [2] can be defined as follows. The states of this model are graphs consisting of paths of osculating walkers which together cover all the edges of the lattice. The vertices can thus be in two states as shown in fig. 1. To a state consisting of l closed paths (loops) a weight of n^l is assigned. We consider exclusively the case $n = 1$, in which all configurations have equal weight. The probability that a vertex is in a particular state is thus $\frac{1}{2}$, irrespective of the states the other vertices are in. Therefore, any problem involving any finite number of osculating walkers can always be reformulated as a computation of a probability in the O(1) loop model. In particular the probability distribution for the path of a single osculating walker are precisely that of finding precisely that path in the O(1) loop model.

Recently, a number of conjectures about correlations of this model have been obtained. These involve probabilities that loops intersect a horizontal cut between vertices (henceforth referred to as a row) in a certain prescribed way. A row intersects loops at a total of L points. We define the connectivity state of the row as the way these L points are connected to each other by the loops via the half cylinder below the row. See fig. 2 for an example.

Fig. 2: Part of a typical configuration of the O(1) loop model on a $6 \times \infty$ cylinder, periodic in the horizontal direction and extending to infinity in both vertical directions. The connectivity state of the half cylinder below the row indicated by the dashed line is $()^3$, above the row it is $)()()$.

Following [10] we represent connectivity states by a string of parentheses. If a point at position i is connected to a point at position j , then this is represented by a parenthesis at position i matching with a parenthesis at position j . Because of periodic boundary conditions a left parenthesis doesn't have to be at the left of the matching right parenthesis. The expression $(\dots)_k$ shall stand for $((\dots))_k$, where k delimiters have been opened and closed, and the dots symbolize an arbitrary well nested configuration. For instance $((()))$ will be denoted as $()_3$, and $((() ()))$ will be denoted as $(() ()_2)_2$. We will omit subscripts equal to 1. With a superscript we will denote a repeated concatenation of a structure with itself. For instance $()_2^k$ stands for a sequence of k $()_2$: $()_2 ()_2 \dots$

A quantity of interest is the probability distribution over the set of all connectivity states. We denote the probability of finding a row in connectivity state c as $P[c]$. Denoting the conditional probability that a row is in state c_1 if the row below is in state c_2 as $P[c_1|c_2]$, we can write:

$$\sum_{c_2} P[c_1|c_2]P[c_2] = P[c_1] \quad (1)$$

For finite L , the conditional probabilities $P[c_1|c_2]$ can be constructed by counting how many times state c_1 can be obtained from c_2 , by continuing the lines to the next row in all possible ways. According to (1) the probability distribution $P[c]$ is the right eigenvector of the matrix $P[c_1|c_2]$. For L not too large $P[c]$ is thus easily obtained. Computations of $P[c]$ for L up to 18 have led to several conjectures [1, 13, 14, 5, 10].

A recent summary of these results is given in [5]. Here we review a few of these conjectures: (i) The connectivity with the smallest probability is $(\)_{L/2}$. (ii) The probability of any other connectivity is an integer multiple of the probability of $(\)_{L/2}$. The reciprocals of $P[(\)_{L/2}]$ for $L = 2, 4, 6, 8, 10, 12, \dots$ are: 2, 10, 140, 5544, 622908, 198846076, ... This is a well known integer sequence. It is given by the number of $L \times L$ alternating sign matrices invariant under a half turn [15]. It is thus conjectured that (iii):

$$P[(\)_{L/2}] = [A_{HT}(L)]^{-1} \tag{2}$$

Here $A_{HT}(L)$ is given by [8]:

$$A_{HT}(L) = 2 \prod_{k=1}^{L/2-1} \frac{3(3k+2)!(3k-1)!k!(k-1)!}{4(2k+1)!(2k-1)!^2} \tag{3}$$

(iv) The event $(\)^{L/2}$ has the largest probability. The ratios $P[(\)^{L/2}]/P[(\)_{L/2}]$ for $L = 2, 4, 6, 8, 10, 12, \dots$ are: 1, 3, 25, 588, 39204, 7422987, ... This integer sequence is given by the number of $(L-1) \times (L-1)$ alternating sign matrices invariant under a half turn [15], so that (v):

$$P[(\)^{L/2}] = \frac{A_{HT}(L-1)}{A_{HT}(L)} \tag{4}$$

The conjectured expression for $A_{HT}(L-1)$ (note that $L-1$ is odd) is given by [15]:

$$A_{HT}(L-1) = \prod_{j=1}^{L/2-1} \frac{4(3j)!^2 j!^2}{3(2j)!^4} \tag{5}$$

Many more conjectures concerning this probability distribution have been obtained, also for other boundary conditions.

2 Bulk Connectivity States

A connectivity state, as defined in the previous section, specifies how points are connected to each other below a certain row. This concerns only configurations on the half cylinder. A convenient way to compute probabilities at a row on the complete cylinder is to consider separately the connectivity states on both half spaces below and above the row. We define the bulk connectivity at a certain row as the pair $\{c_1, c_2\}$, where c_1 (c_2) is the connectivity state below (above) the row. The fact that all loop configurations are equally likely in the $O(1)$ loop model implies that the probability P_b of having the bulk connectivity $\{c_1, c_2\}$ factorizes:

$$P_b[\{c_1, c_2\}] = P[c_1]P[c_2] \tag{6}$$

The probability that a row is intersected by a loop in a certain way directly translates to the probability that a single osculating walker intersects a row in that way. We have obtained the following conjectures concerning single osculating walkers:

- The probability that an osculating walker will visit the left neighbor of the starting point is:

$$\frac{11L^2 + 4}{16(L^2 - 1)} \quad (7)$$

- The probability that the path of an osculating walker winds round the cylinder is given as:

$$\frac{A(L)}{A_{\text{HT}}(L)^2} \quad (8)$$

where $A(L)$ is the number of $L \times L$ alternating sign matrices [8, 16], given by:

$$A(L) = \prod_{j=0}^{L-1} \frac{(3j+1)!}{(L+j)!} \quad (9)$$

For large L this last probability decays as $L^{-1/4}$.

So far we have only considered cylinders with even circumferences L . If L is odd, one has to modify the definition of the connectivity states. On the top row of a half infinite cylinder there will be one point that is not connected to any other point on the row. This point will thus be on an "open" loop spanning the length of the cylinder. This implies that no loop can wind round the cylinder, because any such loop must necessarily cross the open loop, an event not allowed in the $O(1)$ loop model. Interestingly, we conjecture that the probability that a point on an odd L cylinder is visited by this open loop is given by the same formula (8) which for even L gives the probability that a point is on a loop spanning the circumference of the cylinder.

3 Probability of being surrounded by m loops

We have succeeded in guessing an exact formula for the probability $P(L, m)$ that a face of the lattice on a cylinder of circumference L is surrounded by m loops. Writing $P(L, m) = Q(L, m) / A_{\text{HT}}(L)^2$, we conjecture that $Q(L, m)$ is an integer given by:

$$Q(L, m) = C_{L/2-m}(L) + \sum_{r=1}^{L/4-m/2} (-1)^r C_{L/2-m-2r}(L) \frac{m+2r}{m+r} \binom{m+r}{r} \quad (10)$$

Here the $C_p(L)$ are the absolute values of the coefficients of the characteristic polynomial of the $L \times L$ Pascal matrix:

$$\det_{1 \leq r, s \leq L} \left[\binom{r+s-2}{r-1} - x \delta_{r,s} \right] = \sum_{n=0}^L C_n(L) (-x)^n \quad (11)$$

The large L behavior of the $C_p(L)$ is not known well enough to be able to extract the asymptotics of $P(L, m)$ from them. The form of the asymptotics of the $P(L, m)$ can be obtained, however, by applying Coulomb gas techniques to the dense $O(n)$ loop model. On the basis of these (non-rigorous) methods, explained in [11, 12], it is believed [6] that $P(L, 0)$ behaves asymptotically as:

$$P(L, 0) = L^{-5/48} \sum_{k=0}^{\infty} a_k L^{-k/2} \quad (12)$$

In this sum $a_1 = a_2 = a_5 = a_6 = 0$, consistent with the renormalization group prediction.

It is possible to write $Q(L, 0)$ as a binomial determinant as follows. Observe that according to (10):

$$Q(L, 0) = C_{L/2}(L) + 2 \sum_{r=1}^{L/4} (-1)^r C_{L/2-2r}(L) \tag{13}$$

The relation $C_{L/2+p}(L) = C_{L/2-p}(L)$ (see [9]) allows one to rewrite this as

$$Q(L, 0) = \sum_{k=0}^L C_k(L) i^{k-L/2} = i^{-L/2} \det_{1 \leq r,s \leq L} \left[\binom{r+s-2}{r-1} + i\delta_{r,s} \right] \tag{14}$$

It thus follows from (12) that

$$\det_{1 \leq r,s \leq L} \left[\binom{r+s-2}{r-1} + i\delta_{r,s} \right] = i^{L/2} L^{-5/48} A_{HT}(L)^2 \sum_{k=0}^{\infty} a_k L^{-k/2} \tag{15}$$

The first few nonzero coefficients in this expansion are approximately:

$$a_0 \approx 0.81099753, \quad a_3 \approx -0.028861, \quad a_4 \approx 0.021012.$$

The determinant in (15) can be interpreted in terms of cyclically symmetric plane partitions. A plane partition of an integer N is an array of integers $n_{j,k}$, such that $n_{j,k} \geq n_{j+1,k}$, $n_{j,k} \geq n_{j,k+1}$ and $N = \sum_{j=1}^{\infty} \sum_{k=1}^{\infty} n_{j,k}$. Plane partitions can be represented as a pile of unit cubes by introducing x, y, z -coordinates in \mathbb{Z}^3 , and placing at position $(j, k, 0)$ a stack of $n_{j,k}$ cubes. A cyclically symmetric plane partition is a plane partition whose representation as a pile of cubes is invariant under a cyclic permutation of the x, y, z coordinates. In [4] it is shown that determinants of the form

$$\det_{1 \leq r,s \leq L} \left[\binom{r+s-2}{r-1} + \omega \delta_{r,s} \right] \tag{16}$$

give a weighted enumeration of cyclically symmetric plane partitions in an $L \times L \times L$ box. The weight assigned to a plane partition is ω^n , where n is the number of unit cubes on the main diagonal. In [4] closed form expressions of this determinant are given and proved for the cases $\omega^6 = 1$.

We close by using the determinant evaluation for $\omega = \exp(i\pi/3)$ to show that the conjectured expression for $P(L, m)$ is properly normalized. The conjecture (10) can be written as:

$$\sum_{m=0}^{L/2} Q(L, m) = \sum_{k=0}^{L/2} B_k C_{L/2-k}(L) \quad \text{where } B_0 = 1 \text{ and } B_n = \sum_{r=0}^{n/2} (-1)^r \frac{n}{n-r} \binom{n-r}{r} \tag{17}$$

for $n \geq 1$. The summand of (17), which we name $f(n, r)$, satisfies the recurrence:

$$f(n+2, r+1) - f(n+1, r+1) + f(n, r) = 0 \tag{18}$$

Summing this over r from 0 to $n/2$ yields the following recurrence: $B_{n+2} - B_{n+1} + B_n = 0$. From (17) it follows that $B_1 = 1$ and $B_2 = -1$. This yields $B_n = 2 \cos(\pi n/3)$. Inserting this in (17) and using the relation $C_{L/2+p}(L) = C_{L/2-p}(L)$ [9] yields:

$$\sum_{m=0}^{L/2} Q(L, m) = \exp(-i\pi L/6) \det_{1 \leq r,s \leq L} \left[\binom{r+s-2}{r-1} + \exp(i\pi/3) \delta_{r,s} \right] \tag{19}$$

The r.h.s. of (19) should equal $A_{HT}(L)^2$. Using theorem 13 of [4] we verified that this is indeed the case.

4 Conclusion

We have introduced so-called osculating walkers, defined as nonintersecting random walkers that at each vertex can make a left or right turn. These two possibilities are equally likely, unless the vertex has been visited before, in which case the walker leaves the vertex via the unused edge. We have obtained several conjectures about such random walks on a cylinder. Also we have obtained a conjecture for the asymptotics of the determinant $\det_{1 \leq r, s \leq L} \left[\binom{r+s-2}{r-1} + i\delta_{r,s} \right]$.
